A Primer on Memory Consistency and Cache Coherence

Synthesis Lectures on Computer Architecture

Editor

Mark D. Hill, *University of Wisconsin*

Synthesis Lectures on Computer Architecture publishes 50- to 100-page publications on topics pertaining to the science and art of designing, analyzing, selecting and interconnecting hardware components to create computers that meet functional, performance and cost goals. The scope will largely follow the purview of premier computer architecture conferences, such as ISCA, HPCA, MICRO, and ASPLOS.

SYNTHESIS LECTURES ON COMPUTER ARCHITECTURE #16

MORGAN & CLAYPOOL PUBLISHERS

ABSTRACT

Many modern computer systems and most multicore chips (chip multiprocessors) support shared memory in hardware. In a shared memory system, each of the processor cores may read and write to a single shared address space. For a shared memory machine, the memory consistency model defines the architecturally visible behavior of its memory system. Consistency definitions provide rules about loads and stores (or memory reads and writes) and how they act upon memory. As part of supporting a memory consistency model, many machines also provide cache coherence protocols that ensure that multiple cached copies of data are kept up-to-date. The goal of this primer is to provide readers with a basic understanding of consistency and coherence. This understanding includes both the issues that must be solved as well as a variety of solutions. We present both high-level concepts as well as specific, concrete examples from real-world systems.

KEYWORDS

computer architecture, memory consistency, cache coherence, shared memory, memory systems, multicore processor, multiprocessor

Preface

This primer is intended for readers who have encountered memory consistency and cache coherence informally, but now want to understand what they entail in more detail. This audience includes computing industry professionals as well as junior graduate students.

We expect our readers to be familiar with the basics of computer architecture. Remembering the details of Tomasulo’s algorithm or similar details is unnecessary, but we do expect readers to understand issues like architectural state, dynamic instruction scheduling (out-of-order execution), and how caches are used to reduce average latencies to access storage structures.

The primary goal of this primer is to provide readers with a basic understanding of consistency and coherence. This understanding includes both the issues that must be solved as well as a variety of solutions. We present both high-level concepts as well as specific, concrete examples from real-world systems. A secondary goal of this primer is to make readers aware of just how complicated consistency and coherence are. If readers simply discover what it is that they do not know—without actually learning it—that discovery is still a substantial benefit. Furthermore, because these topics are so vast and so complicated, it is beyond the scope of this primer to cover them exhaustively. It is *not* a goal of this primer to cover all topics in depth, but rather to cover the basics and apprise the readers of what topics they may wish to pursue in more depth.

We owe many thanks for the help and support we have received during the development of this primer. We thank Blake Hechtman for implementing and testing (and debugging!) all of the coherence protocols in this primer. As the reader will soon discover, coherence protocols are complicated, and we would not have trusted any protocol that we had not tested, so Blake’s work was tremendously valuable. Blake implemented and tested all of these protocols using the Wisconsin GEMS simulation infrastructure [<http://www.cs.wisc.edu/gems/>].

For reviewing early drafts of this primer and for helpful discussions regarding various topics within the primer, we gratefully thank Trey Cain and Milo Martin. For providing additional feedback on the primer, we thank Newsha Ardalani, Arkaprava Basu, Brad Beckmann, Bob Cypher, Joe Devietti, Sandip Govind Dhoot, Alex Edelsburg, Jayneel Gandhi, Dan Gibson, Marisabel Guevara, Gagan Gupta, Blake Hechtman, Derek Hower, Zachary Marzec, Hiran Mayukh, Ralph Nathan, Marc Orr, Vijay Sathish, Abhirami Senthilkumaran, Simha Sethumadhavan, Venkatanathan

Varadarajan, Derek Williams, and Meng Zhang. While our reviewers provided great feedback, they may or may not agree with all of the final contents of this primer.

This work is supported in part by the National Science Foundation (CNS-0551401, CNS-0720565, CCF-0916725, CCF-0444516, and CCF-0811290), Sandia/DOE (#MSN123960/DOE890426), Semiconductor Research Corporation (contract 2009-HJ-1881), and the University of Wisconsin (Kellett Award to Hill). The views expressed herein are not necessarily those of the NSF, Sandia, DOE, or SRC.

Dan thanks Deborah, Jason, and Julie for their love and for putting up with him taking the time to work on another synthesis lecture. Dan thanks his Uncle Sol for helping inspire him to be an engineer in the first place. Lastly, Dan dedicates this book to the memory of Rusty Sneiderman, a treasured friend of thirty years who will be dearly missed by everyone who was lucky enough to have known him.

Mark wishes to thank Sue, Nicole, and Gregory for their love and support.

David thanks his coauthors for putting up with his deadline-challenged work style, his parents Roger and Ann Wood for inspiring him to be a second-generation Computer Sciences professor, and Jane, Alex, and Zach for helping him remember what life is all about.

CHAPTER 1

Introduction to Consistency and Coherence

Many modern computer systems and most multicore chips (chip multiprocessors) support shared memory in hardware. In a shared memory system, each of the processor cores may read and write to a single shared address space. These designs seek various goodness properties, such as high performance, low power, and low cost. Of course, it is not valuable to provide these goodness properties without first providing correctness. Correct shared memory seems intuitive at a hand-wave level, but, as this lecture will help show, there are subtle issues in even defining what it means for a shared memory system to be correct, as well as many subtle corner cases in designing a correct shared memory implementation. Moreover, these subtleties must be mastered in hardware implementations where bug fixes are expensive. Even academics should master these subtleties to make it more likely that their proposed designs will work.

We and many others find it useful to separate shared memory correctness into two sub-issues: *consistency and coherence*. Computer systems are not required to make this separation, but we find it helps to divide and conquer complex problems, and this separation prevails in many real shared memory implementations.

It is the job of consistency (memory consistency, memory consistency model, or memory model) to define shared memory correctness. Consistency definitions provide rules about loads and stores (or memory reads and writes) and how they act upon memory. Ideally, consistency definitions would be simple and easy to understand. However, defining what it means for shared memory to behave correctly is more subtle than defining the correct behavior of, for example, a single-threaded processor core. The correctness criterion for a single processor core partitions behavior between one correct result and many incorrect alternatives. This is because the processor's architecture mandates that the execution of a thread transforms a given input state into a single well-defined output state, even on an out-of-order core. Shared memory consistency models, however, concern the loads and stores of multiple threads and usually allow many correct executions while disallowing many (more) incorrect ones. The possibility of multiple correct executions is due to the ISA allowing multiple threads to execute concurrently, often with many possible legal interleavings of instructions from

2 A PRIMER ON MEMORY CONSISTENCY AND CACHE COHERENCE

different threads. The multitude of correct executions complicates the erstwhile simple challenge of determining whether an execution is correct. Nevertheless, consistency must be mastered to implement shared memory and, in some cases, to write correct programs that use it.

Unlike consistency, coherence (or cache coherence) is neither visible to software nor required. However, as part of supporting a consistency model, the vast majority of shared memory systems implement a coherence protocol that provides coherence. Coherence seeks to make the caches of a shared-memory system as functionally invisible as the caches in a single-core system. Correct coherence ensures that a programmer cannot determine whether and where a system has caches by analyzing the results of loads and stores. This is because correct coherence ensures that the caches never enable new or different *functional* behavior (programmers may still be able to infer likely cache structure using *timing* information).

In most systems, coherence protocols play an important role in providing consistency. Thus, even though consistency is the first major topic of this primer, we begin in Chapter 2 with a brief introduction to coherence. The goal of this chapter is to explain enough about coherence to understand how consistency models interact with coherent caches, but not to explore specific coherence protocols or implementations, which are topics we defer until the second portion of this primer in Chapters 6–9. In Chapter 2, we define coherence using the single-writer–multiple-reader (SWMR) invariant. SWMR requires that, at any given time, a memory location is either cached for writing (and reading) at one cache or cached only for reading at zero to many caches.

1.1 CONSISTENCY (A.K.A., MEMORY CONSISTENCY, MEMORY CONSISTENCY MODEL, OR MEMORY MODEL)

Consistency models define correct shared memory behavior in terms of loads and stores (memory reads and writes), without reference to caches or coherence. To gain some real-world intuition on why we need consistency models, consider a university that posts its course schedule online. Assume that the Computer Architecture course is originally scheduled to be in Room 152. The day before classes begin, the university registrar decides to move the class to Room 252. The registrar sends an e-mail message asking the web site administrator to update the online schedule, and a few minutes later, the registrar sends a text message to all registered students to check the newly updated schedule. It is not hard to imagine a scenario—if, say, the web site administrator is too busy to post the update immediately—in which a diligent student receives the text message, immediately checks the online schedule, and still observes the (old) class location Room 152. Even though the online schedule is eventually updated to Room 252 and the registrar performed the “writes” in the correct order, this diligent student observed them in a different order and thus went to the wrong room. A consistency model defines whether this behavior is correct (and thus whether a user must take other

action to achieve the desired outcome) or incorrect (in which case the system must preclude these reorderings).

Although this contrived example used multiple media, similar behavior can happen in shared memory hardware with out-of-order processor cores, write buffers, prefetching, and multiple cache banks. Thus, we need to define shared memory correctness—that is, which shared memory behaviors are allowed—so that programmers know what to expect and implementors know the limits to what they can provide.

Shared memory correctness is specified by a memory consistency model or, more simply, a memory model. The memory model specifies the allowed behavior of multithreaded programs executing with shared memory. For a multithreaded program executing with specific input data, the memory model specifies what values dynamic loads may return and what possible final states of the memory are. Unlike single-threaded execution, multiple correct behaviors are usually allowed, making understanding memory consistency models subtle.

Chapter 3 introduces the concept of memory consistency models and presents sequential consistency (SC), the strongest and most intuitive consistency model. The chapter begins by motivating the need to specify shared memory behavior and precisely defines what a memory consistency model is. It next delves into the intuitive SC model, which states that a multithreaded execution should look like an interleaving of the sequential executions of each constituent thread, as if the threads were time-multiplexed on a single-core processor. Beyond this intuition, the chapter formalizes SC and explores implementing SC with coherence in both simple and aggressive ways, culminating with a MIPS R10000 case study.

In Chapter 4, we move beyond SC and focus on the memory consistency model implemented by x86 and SPARC systems. This consistency model, called total store order (TSO), is motivated by the desire to use first-in–first-out write buffers to hold the results of committed stores before writing the results to the caches. This optimization violates SC, yet promises enough performance benefit to inspire architectures to define TSO, which permits this optimization. In this chapter, we show how to formalize TSO from our SC formalization, how TSO affects implementations, and how SC and TSO compare.

Finally, Chapter 5 introduces “relaxed” or “weak” memory consistency models. It motivates these models by showing that most memory orderings in strong models are unnecessary. If a thread updates ten data items and then a synchronization flag, programmers usually do not care if the data items are updated in order with respect to each other but only that all data items are updated before the flag is updated. Relaxed models seek to capture this increased ordering flexibility to get higher performance or a simpler implementation. After providing this motivation, the chapter develops an example relaxed consistency model, called XC, wherein programmers get order only when they

4 A PRIMER ON MEMORY CONSISTENCY AND CACHE COHERENCE

ask for it with a FENCE instruction (e.g., a FENCE after the last data update but before the flag write). The chapter then extends the formalism of the previous two chapters to handle XC and discusses how to implement XC (with considerable reordering between the cores and the coherence protocol). The chapter then discusses a way in which many programmers can avoid thinking about relaxed models directly: if they add enough FENCES to ensure their program is data-race free (DRF), then most relaxed models will appear SC. With “SC for DRF,” programmers can get both the (relatively) simple correctness model of SC with the (relatively) higher performance of XC. For those who want to reason more deeply, the chapter concludes by distinguishing acquires from releases, discussing write atomicity and causality, pointing to commercial examples (including an IBM Power case study), and touching upon high-level language models (Java and C++).

Returning to the real-world consistency example of the class schedule, we can observe that the combination of an email system, a human web administrator, and a text-messaging system represents an extremely weak consistency model. To prevent the problem of a diligent student going to the wrong room, the university registrar needed to perform a FENCE operation after her email to ensure that the online schedule was updated before sending the text message.

1.2 COHERENCE (A.K.A., CACHE COHERENCE)

Unless care is taken, a coherence problem can arise if multiple actors (e.g., multiple cores) have access to multiple copies of a datum (e.g., in multiple caches) and at least one access is a write. Consider an example that is similar to the memory consistency example. A student checks the online schedule of courses, observes that the Computer Architecture course is being held in Room 152 (reads the datum), and copies this information into her notebook (caches the datum). Subsequently, the university registrar decides to move the class to Room 252 and updates the online schedule (writes to the datum). The student’s copy of the datum is now stale, and we have an incoherent situation. If she goes to Room 152, she will fail to find her class. Examples of incoherence from the world of computing, but not including computer architecture, include stale web caches and programmers using un-updated code repositories.

Access to stale data (incoherence) is prevented using a coherence protocol, which is a set of rules implemented by the distributed set of actors within a system. Coherence protocols come in many variants but follow a few themes, as developed in Chapters 6–9.

Chapter 6 presents the big picture of cache coherence protocols and sets the stage for the subsequent chapters on specific coherence protocols. This chapter covers issues shared by most coherence protocols, including the distributed operations of cache controllers and memory controllers and the common MOESI coherence states: modified (M), owned (O), exclusive (E), shared (S), and invalid (I). Importantly, this chapter also presents our table-driven methodology for presenting protocols with both stable (e.g., MOESI) and transient coherence states. Transient states are required

in real implementations because modern systems rarely permit atomic transitions from one stable state to another (e.g., a read miss in state Invalid will spend some time waiting for a data response before it can enter state Shared). Much of the real complexity in coherence protocols hides in the transient states, similar to how much of processor core complexity hides in micro-architectural states.

Chapter 7 covers snooping cache coherence protocols, which dominated the commercial market until fairly recently. At the hand-wave level, snooping protocols are simple. When a cache miss occurs, a core's cache controller arbitrates for a shared bus and broadcasts its request. The shared bus ensures that all controllers observe all requests in the same order and thus all controllers can coordinate their individual, distributed actions to ensure that they maintain a globally consistent state. Snooping gets complicated, however, because systems may use multiple buses and modern buses do not atomically handle requests. Modern buses have queues for arbitration and can send responses that are unicast, delayed by pipelining, or out-of-order. All of these features lead to more transient coherence states. Chapter 7 concludes with case studies of the Sun UltraEnterprise E10000 and the IBM Power5.

Chapter 8 delves into directory cache coherence protocols that offer the promise of scaling to more processor cores and other actors than snooping protocols that rely on broadcast. There is a joke that all problems in computer science can be solved with a level of indirection. Directory protocols support this joke: A cache miss requests a memory location from the next level cache (or memory) controller, which maintains a directory that tracks which caches hold which locations. Based on the directory entry for the requested memory location, the controller sends a response message to the requestor or forwards the request message to one or more actors currently caching the memory location. Each message typically has one destination (i.e., no broadcast or multicast), but transient coherence states abound as transitions from one stable coherence state to another stable one can generate a number of messages proportional to the number of actors in the system. This chapter starts with a basic directory protocol and then refines it to handle the MOESI states E and O, distributed directories, less stalling of requests, approximate directory entry representations, and more. The chapter also explores the design of the directory itself, including directory caching techniques. The chapter concludes with case studies of the old SGI Origin 2000 and the newer AMD HyperTransport, HyperTransport Assist, and Intel QuickPath Interconnect (QPI).

Chapter 9 deals with some, but not all, of the advanced topics in coherence. For ease of explanation, the prior chapters on coherence intentionally restrict themselves to the simplest system models needed to explain the fundamental issues. Chapter 9 delves into more complicated system models and optimizations, with a focus on issues that are common to both snooping and directory protocols. Initial topics include dealing with instruction caches, multilevel caches, write-through caches, translation lookaside buffers (TLBs), coherent direct memory access (DMA), virtual caches,

and hierarchical coherence protocols. Finally, the chapter delves into performance optimizations (e.g., targeting migratory sharing and false sharing) and directly maintaining the SWMR invariant with token coherence.

1.3 A CONSISTENCY AND COHERENCE QUIZ

It can be easy to convince oneself that one's knowledge of consistency and coherence is sufficient and that reading this primer is not necessary. To test whether this is the case, we offer this pop quiz.

- Question 1: In a system that maintains sequential consistency, a core must issue coherence requests in program order. True or false? (Answer is in Section 3.8)
- Question 2: The memory consistency model specifies the legal orderings of coherence transactions. True or false? (Section 3.8)
- Question 3: To perform an atomic read–modify–write instruction (e.g., test-and-set), a core must always communicate with the other cores. True or false? (Section 3.9)
- Question 4: In a TSO system with multithreaded cores, threads may bypass values out of the write buffer, regardless of which thread wrote the value. True or false? (Section 4.4)
- Question 5: A programmer who writes properly synchronized code relative to the high-level language's consistency model (e.g., Java) does not need to consider the architecture's memory consistency model. True or false? (Section 5.9)
- Question 6: In an MSI snooping protocol, a cache block may only be in one of three coherence states. True or false? (Section 7.2)
- Question 7: A snooping cache coherence protocol requires the cores to communicate on a bus. True or false? (Section 7.6)

Even though the answers are provided later in this primer, we encourage readers to try to answer the questions before looking ahead at the answers.

1.4 WHAT THIS PRIMER DOES NOT DO

This lecture is intended to be a primer on coherence and consistency. We expect this material could be covered in a graduate class in about nine 75-minute classes, e.g., one lecture per Chapter 2 to Chapter 9 plus one lecture for advanced material).

For this purpose, there are many things the primer does *not* cover. Some of these include:

- Synchronization. Coherence makes caches invisible. Consistency can make shared memory look like a single memory module. Nevertheless, programmers will probably need locks, barriers, and other synchronization techniques to make their programs useful.

- Commercial Relaxed Consistency Models. This primer does not cover all the subtleties of the ARM and PowerPC memory models, but does describe which mechanisms they provide to enforce order.
- Parallel programming. This primer does not discuss parallel programming models, methodologies, or tools.

CHAPTER 2

Coherence Basics

In this chapter, we introduce enough about cache coherence to understand how consistency models interact with caches. We start in Section 2.1 by presenting the system model that we consider throughout this primer. To simplify the exposition in this chapter and the following chapters, we select the simplest possible system model that is sufficient for illustrating the important issues; we defer until Chapter 9 issues related to more complicated system models. Section 2.2 explains the cache coherence problem that must be solved and how the possibility of incoherence arises. Section 2.3 precisely defines cache coherence.

2.1 BASELINE SYSTEM MODEL

In this primer, we consider systems with multiple processor cores that share memory. That is, all cores can perform loads and stores to all (physical) addresses. The baseline system model includes a single multicore processor chip and off-chip main memory, as illustrated in Figure 2.1. The multicore processor chip consists of multiple single-threaded cores, each of which has its own private data cache, and a last-level cache (LLC) that is shared by all cores. Throughout this primer, when we use the term “cache,” we are referring to a core’s private data cache and not the LLC. Each core’s data cache is accessed with physical addresses and is write-back. The cores and the LLC communicate with each other over an interconnection network. The LLC, despite being on the processor chip, is logically a “memory-side cache” and thus does not introduce another level of coherence issues. The LLC is logically just in front of the memory and serves to reduce the average latency of memory accesses and increase the memory’s effective bandwidth. The LLC also serves as an on-chip memory controller.

This baseline system model omits many features that are common but that are not required for purposes of most of this primer. These features include instruction caches, multiple-level caches, caches shared among multiple cores, virtually addressed caches, TLBs, and coherent direct memory access (DMA). The baseline system model also omits the possibility of multiple multicore chips. We will discuss all of these features later, but for now, they would add unnecessary complexity.

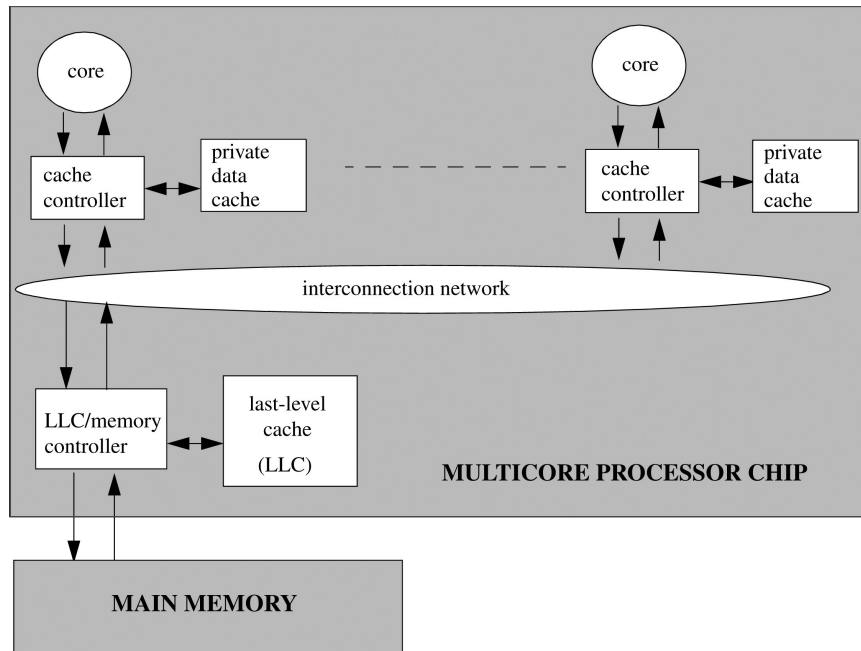

FIGURE 2.1: Baseline system model used throughout this primer.

2.2 THE PROBLEM: HOW INCOHERENCE COULD POSSIBLY OCCUR

The possibility of incoherence arises only because of one fundamental issue: there exist multiple actors with access to caches and memory. In modern systems, these actors are processor cores, DMA engines, and external devices that can read and/or write to caches and memory. In the rest of this primer, we generally focus on actors that are cores, but it is worth keeping in mind that other actors may exist.

Figure 2.2 illustrates a simple example of incoherence. Initially, memory location A has the value 42 in memory, and then both Core 1 and Core 2 load this value from memory into their respective caches. At time 3, Core 1 increments the value at memory location A from 42 to 43 in its cache, making Core 2's value of A in its cache stale or incoherent. To prevent incoherence, the system must implement a *cache coherence protocol* to regulate the actions of the cores such that Core 2 cannot observe the old value of 42 at the same time that Core 1 observes the value 43. The design and implementation of these cache coherence protocols are the main topics of Chapter 7 through Chapter 9.

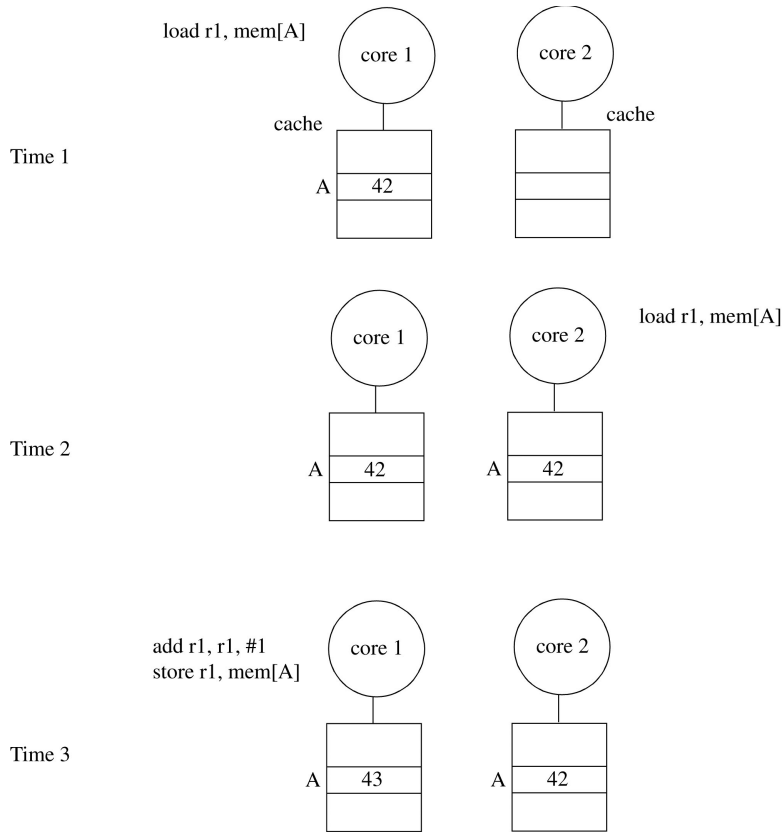

FIGURE 2.2: Example of incoherence. Assume the value of memory at memory location A is initially 2.

2.3 DEFINING COHERENCE

The example of an incoherent situation described in Section 2.2 is intuitively “incorrect” in that actors observe different values of a given datum at the same time. In this section, we transition from an intuitive sense of what is incoherent to a precise definition of coherence. There are several definitions of coherence that have appeared in textbooks and in published papers, and we do not wish to present all of them. Instead, we present the definition we prefer for its insight into the design of coherence protocols. In the sidebar, we discuss alternative definitions and how they relate to our preferred definition.

FIGURE 2.3: Dividing a given memory location’s lifetime into epochs

The basis of our preferred definition of coherence is the *single-writer–multiple-reader (SWMR)* invariant. For any given memory location, at any given moment in time,¹ there is either a single core that may write it (and that may also read it) or some number of cores that may read it. Thus, there is never a time when a given memory location may be written by one core and simultaneously either read or written by any other cores. Another way to view this definition is to consider, for each memory location, that the memory location’s lifetime is divided up into epochs. In each epoch, either a single core has read–write access or some number of cores (possibly zero) have read-only access. Figure 2.3 illustrates the lifetime of an example memory location, divided into four epochs that maintain the SWMR invariant.

In addition to the SWMR invariant, coherence requires that the value of a given memory location is propagated correctly. To explain why values matter, let us reconsider the example in Figure 2.3. Even though the SWMR invariant holds, if during the first read-only epoch Cores 2 and 5 can read different values, then the system is not coherent. Similarly, the system is incoherent if Core 1 fails to read the last value written by Core 3 during its read–write epoch or any of Cores 1, 2, or 3 fail to read the last write performed by Core 1 during its read–write epoch.

Thus, the definition of coherence must augment the SWMR invariant with a data value invariant that pertains to how values are propagated from one epoch to the next. This invariant states that the value of a memory location at the start of an epoch is the same as the value of the memory location at the end of its last read–write epoch.

There are other interpretations of these invariants that are equivalent. One notable example [5] interpreted the SMWR invariants in terms of tokens. The invariants are as follows. For each memory location, there exists a fixed number of tokens that is at least as large as the number of cores. If a core has all of the tokens, it may write the memory location. If a core has one or more tokens, it may read the memory location. At any given time, it is thus impossible for one core to be writing the memory location while any other core is reading or writing it.

¹The SWMR invariant need only be maintained in *logical time*, not physical time. This subtle issue enables many optimizations that appear to—but do not—violate this invariant. We defer discussion of these optimizations until later chapters, and readers unfamiliar with logical time should not be concerned.

Coherence invariants

1. **Single-Writer, Multiple-Read (SWMR) Invariant.** For any memory location A , at any given (logical) time, there exists only a single core that may write to A (and can also read it) or some number of cores that may only read A .
2. **Data-Value Invariant.** The value of the memory location at the start of an epoch is the same as the value of the memory location at the end of its last read–write epoch.

2.3.1 Maintaining the Coherence Invariants

The coherence invariants presented in the previous section provide some intuition into how coherence protocols work. The vast majority of coherence protocols, called “invalidate protocols,” are designed explicitly to maintain these invariants. If a core wants to read a memory location, it sends messages to the other cores to obtain the current value of the memory location and to ensure that no other cores have cached copies of the memory location in a read–write state. These messages end any active read–write epoch and begin a read-only epoch. If a core wants to write to a memory location, it sends messages to the other cores to obtain the current value of the memory location, if it does not already have a valid read-only cached copy, and to ensure that no other cores have cached copies of the memory location in either read-only or read–write states. These messages end any active read–write or read-only epoch and begin a new read–write epoch. This primer’s chapters on cache coherence (Chapters 6–9) expand greatly upon this abstract description of invalidate protocols, but the basic intuition remains the same.

2.3.2 The Granularity of Coherence

A core can perform loads and stores at various granularities, often ranging from 1 to 64 bytes. In theory, coherence could be performed at the finest load/store granularity. However, in practice, coherence is usually maintained at the granularity of cache blocks. That is, the hardware enforces coherence on a cache block by cache block basis. In practice, the SWMR invariant is likely to be that, for any *block* of memory, there is either a single writer or some number of readers. In typical systems, it is not possible for one core to be writing to the first byte of a block while another core is writing to another byte within that block. Although cache-block granularity is common, and it is what we assume throughout the rest of this primer, one should be aware that there have been protocols that have maintained coherence at finer and coarser granularities.

Sidebar: Consistency-Like Definitions of Coherence

Our preferred definition of coherence specifies invariants regarding the access permissions of different cores to a memory location and the data values passed between cores that have particular permissions. There exists another class of definitions that focuses on loads and stores, similar to how memory consistency models specify architecturally visible orderings of loads and stores.

One consistency-like approach to specifying coherence is related to the definition of sequential consistency. Sequential consistency (SC), a memory consistency model that we discuss in great depth in Chapter 3, specifies that the system must appear to execute all threads' loads and stores to all memory locations in a total order that respects the program order of each thread. Each load gets the value of the most recent store in that total order. A definition of coherence that is analogous to the definition of SC is that a coherent system must appear to execute all threads' loads and stores to a single memory location in a total order that respects the program order of each thread. This definition highlights an important distinction between coherence and consistency: coherence is specified on a per-memory location basis, whereas consistency is specified with respect to all memory locations.

Another definition [1,2] of coherence defines coherence with two invariants: (1) every store is eventually made visible to all cores, and (2) writes to the same memory location are serialized (i.e., observed in the same order by all cores). IBM takes a similar view in the Power architecture [4], in part to facilitate implementations in which a sequence of stores by one core may have reached some cores (their values visible to loads by those coers) but not other cores.

Another definition of coherence, as specified by Hennessy and Patterson [3], consists of three invariants: (1) a load to memory location *A* by a core obtains the value of the previous store to *A* by that core, unless another core has stored to *A* in between, (2) a load to *A* obtains the value of a store *S* to *A* by another core if *S* and the load “are sufficiently separated in time” and if no other store occurred between *S* and the load, and (3) stores to the same memory location are serialized (same as invariant #2 in the previous definition). This set of invariants is intuitive but somewhat problematic in that “sufficiently separated in time” is imprecise.

These consistency-like definitions are just as valid as the definition we presented in Section 2.3 and they can easily be used as specifications against which to verify whether a given protocol enforces coherence. A correct coherence protocol will satisfy any of these definitions. However, the consistency-like definitions tend not to offer much intuition to the architect of a coherence protocol. An architect designs a protocol to regulate how and when cores may access memory locations, and thus we believe the definition in Section 2.3 is more insightful to the architect.

2.3.3 The Scope of Coherence

The definition of coherence—regardless of which definition we choose—has a specific scope, and architects must be aware of when it pertains and when it does not. We now discuss two important scope issues:

- Coherence pertains to *all* storage structures that hold blocks from the shared address space. These structures include the L1 data cache, L2 cache, shared last-level cache (LLC), and main memory. These structures also include the L1 instruction cache and translation lookaside buffers (TLBs).²
- Coherence does not pertain to the architecture (i.e., coherence is not architecturally visible). Strictly speaking, a system could be incoherent and still be correct if it adhered to the specified memory consistency model. Although this issue may seem like an intellectual curiosity (i.e., it is difficult to imagine a practical system that is consistent but not coherent), it has a highly important corollary: the memory consistency model places no explicit constraints on coherence or the protocol used to enforce it. Nonetheless, as discussed in Chapters 3 through 5, many consistency model implementations rely on certain common coherence properties for correctness, which is why we have introduced coherence in this chapter before moving on to discuss consistency models.

²In some architectures, the TLB can hold mappings that are not strictly copies of blocks in shared memory.

CHAPTER 3

Memory Consistency Motivation and Sequential Consistency

This chapter delves into memory consistency models (a.k.a. memory models) that define the behavior of shared memory systems for programmers and implementors. These models define correctness so that programmers know what to expect and implementors know what to provide. We first motivate the need to define memory behavior (Section 3.1), say what a memory consistency model should do (Section 3.2), and compare and contrast consistency and coherence (Section 3.3).

We then explore the (relatively) intuitive model of sequential consistency (SC). SC is important because it is what many programmers expect of shared memory and provides a foundation for understanding the more relaxed (weak) memory consistency models presented in the next two chapters. We first present the basic idea of SC (Section 3.4) and present a formalism of it that we will also use in subsequent chapters (Section 3.5). We then discuss implementations of SC, starting with naive implementations that serve as operational models (Section 3.6), a basic implementation of SC with cache coherence (Section 3.7), more optimized implementations of SC with cache coherence (Section 3.8), and the implementation of atomic operations (Section 3.9). We conclude our discussion of SC by providing a MIPS R10000 case study (Section 3.10) and pointing to some further reading (Section 3.11).

3.1 PROBLEMS WITH SHARED MEMORY BEHAVIOR

To see why shared memory behavior must be defined, consider the example execution of two cores¹ depicted in Table 3.1 (this example, as is the case for all examples in this chapter, assumes that the initial values of all variables are zero). Most programmers would expect that core C2's register r2 should get the value NEW. Nevertheless, r2 can be 0 in some of today's computer systems.

Hardware can make r2 get the value 0 by reordering core C1's stores S1 and S2. Locally (i.e., if we look only at C1's execution and do not consider interactions with other threads), this reordering seems correct because S1 and S2 access different addresses. The sidebar on page 18 describes a

¹Let “core” refer to software's view of a core, which may be an actual core or a thread context of a multithreaded core.

TABLE 3.1: Should r2 Always be Set to NEW?

Core C1	Core C2	Comments
S1: Store data = NEW; S2: Store flag = SET;	L1: Load r1 = flag; B1: if (r1 ≠ SET) goto L1; L2: Load r2 = data;	/* Initially, data = 0 & flag ≠ SET */ /* L1 & B1 may repeat many times */

few of the ways in which hardware might reorder memory accesses, including these stores. Non-hardware experts may wish to trust that such reordering can happen (e.g., with a write buffer that is not first-in–first-out).

With the reordering of S1 and S2, the execution order may be S2, L1, L2, S1, as illustrated in Table 3.2.

Sidebar: How a Core Might Reorder Memory Accesses

This sidebar describes a few of the ways in which modern cores may reorder memory accesses to different addresses. Those unfamiliar with these hardware concepts may wish to skip this on first reading. Modern cores may reorder many memory accesses, but it suffices to reason about reordering two memory operations. In most cases, we need to reason only about a core reordering two memory operations to two different addresses, as the sequential execution (i.e., von Neumann) model generally requires that operations to the same address execute in the original program order. We break the possible reorderings down into three cases based on whether the reordered memory operations are loads or stores.

Store–store reordering. Two stores may be reordered if a core has a non-FIFO write buffer that lets stores depart in a different order than the order in which they entered. This might occur if the first store misses in the cache while the second hits or if the second store can coalesce with an earlier store (i.e., before the first store). Note that these reorderings are possible even if the core executes all instructions in program order. Reordering stores to different memory addresses has no effect on a single-threaded execution. However, in the multithreaded example of Table 3.1, reordering Core C1’s stores allows Core C2 to see flag as SET before it sees the store to data. Note that the problem is not fixed even if the write buffer drains into a perfectly

coherent memory hierarchy. Coherence will make all caches invisible, but the stores are already reordered.

Load-load reordering. Modern dynamically-scheduled cores may execute instructions out of program order. In the example of Table 3.1, Core C2 could execute loads L1 and L2 out of order. Considering only a single-threaded execution, this reordering seems safe because L1 and L2 are to different addresses. However, reordering Core C2's loads behaves the same as reordering Core C1's stores; if the memory references execute in the order L2, S1, S2 and L1, then r2 is assigned 0. This scenario is even more plausible if the branch statement B1 is elided, so no control dependence separates L1 and L2.

Load-store and store-load reordering. Out-of-order cores may also reorder loads and stores (to different addresses) from the same thread. Reordering an earlier load with a later store (a load-store reordering) can cause many incorrect behaviors, such as loading a value after releasing the lock that protects it (if the store is the unlock operation). The example in Table 3-3 illustrates the effect of reordering an earlier store with a later load (a store-load reordering). Reordering Core C1's accesses S1 and L1 and Core C2's accesses S2 and L2 allows the counterintuitive result that both r1 and r2 are 0. Note that store-load reorderings may also arise due to local bypassing in the commonly implemented FIFO write buffer, even with a core that executes all intructions in program order.

A reader might assume that hardware should not permit some or all of these behaviors, but without a better understanding of what behaviors are allowed, it is hard to determine a list of what hardware can and cannot do.

TABLE 3.2: One Possible Execution of Program in Table 3.1.

cycle	Core C1	Core C2	Coherence state of data	Coherence state of flag
1	S2: Store flag=SET		read-only for C2	read-write for C1
2		L1: Load r1=flag	read-only for C2	read-only for C2
3		L2: Load r2=data	read-only for C2	read-only for C2
4	S1: Store data=NEW		read-write for C1	read-only for C2

TABLE 3.3: Can Both r1 and r2 be Set to 0?

Core C1	Core C2	Comments
S1: x = NEW; L1: r1 = y;	S2: y = NEW; L2: r2 = x;	/* Initially, x = 0 & y = 0*/

This execution satisfies coherence because the SWMR property is not violated, so incoherence is not the underlying cause of this seemingly erroneous execution result.

Let us consider another important example inspired by Dekker’s Algorithm for ensuring mutual exclusion, as depicted in Table 3.3. After execution, what values are allowed in r1 and r2? Intuitively, one might expect that there are three possibilities:

- $(r1, r2) = (0, \text{NEW})$ for execution S1, L1, S2, then L2
- $(r1, r2) = (\text{NEW}, 0)$ for S2, L2, S1, and L1
- $(r1, r2) = (\text{NEW}, \text{NEW})$, e.g., for S1, S2, L1, and L2

Surprisingly, most real hardware, e.g., x86 systems from Intel and AMD, also allows $(r1, r2) = (0, 0)$ because it uses first-in–first-out (FIFO) write buffers to enhance performance. As with the example in Table 3.1, all of these executions satisfy cache coherence, even $(r1, r2) = (0, 0)$.

Some readers might object to this example because it is non-deterministic (multiple outcomes are allowed) and may be a confusing programming idiom. However, in the first place, all current multiprocessors are non-deterministic by default; all architectures of which we are aware permit multiple possible interleavings of the executions of concurrent threads. The illusion of determinism is sometimes, but not always, created by software with appropriate synchronization idioms. Thus, we must consider non-determinism when defining shared memory behavior.

Furthermore, memory behavior is usually defined for *all* executions of all programs, even those that are incorrect or intentionally subtle (e.g., for non-blocking synchronization algorithms). In Chapter 5, however, we will see some high-level language models that allow *some* executions to have undefined behavior, e.g., executions of programs with data races.

3.2 WHAT IS A MEMORY CONSISTENCY MODEL?

The examples in the last sub-section illustrate that shared memory behavior is subtle, giving value to precisely defining (a) what behaviors programmers can expect and (b) what optimizations system implementors may use. A memory consistency model disambiguates these issues.

A *memory consistency model*, or, more simply, a *memory model*, is a specification of the allowed behavior of multithreaded programs executing with shared memory. For a multithreaded program executing with specific input data, it specifies what values dynamic loads may return and what the final state of memory is. Unlike a single-threaded execution, multiple correct behaviors are usually allowed, as we will see for sequential consistency (Section 3.4 and beyond).

In general, a memory consistency model MC gives rules that partition executions into those obeying MC (*MC executions*) and those disobeying MC (*non-MC executions*). This partitioning of executions, in turn, partitions implementations. An *MC implementation* is a system that permits only MC executions, while a *non-MC implementation* sometimes permits non-MC executions.

Finally, we have been vague regarding the level of programming. We begin by assuming that programs are executables in a hardware instruction set architecture, and we assume that memory accesses are to memory locations identified by physical addresses (i.e., we are not considering the impact of virtual memory and address translation). In Chapter 5, we will discuss issues with high-level languages (HLLs). We will see then, for example, that a compiler allocating a variable to a register can affect an HLL memory model in a manner similar to hardware reordering memory references.

3.3 CONSISTENCY VS. COHERENCE

Chapter 2 defined cache coherence with two invariants that we informally repeat here. The *Single-Writer-Multiple-Reader (SWMR) invariant* ensures that at any (logical) time for a memory location with a given address, either (a) one core may write (and read) the address or (b) one or more cores may only read it. The *Data-Value Invariant* ensures that updates to the memory location are passed correctly so that cached copies of the memory location always contain the most recent version.

It would seem that cache coherence defines shared memory behavior. It does not for three reasons:

- The goal of cache coherence is to make caches in multicore systems as invisible as caches in single-core systems. However, once caches are invisible, what behavior remains?
- Coherence typically deals with one cache block at a time and is silent on the interaction of accesses to multiple cache blocks. Real programs access variables across numerous cache blocks.
- It is possible to implement a memory system without coherence and even without caches.

Although coherence is not required, most shared memory systems do implement their memory consistency model with coherent caches. Even so, it is possible—and we think extremely valuable—to decouple the consistency implementation from the coherence implementation. To this end, the memory consistency implementations we present in this and the next two chapters will

use coherence like a subroutine call. For example, they will exploit the SWMR invariant without concern for how it is implemented.

In summary:

- Cache coherence does not equal memory consistency.
- A memory consistency implementation can use cache coherence as a useful “black box.”

3.4 BASIC IDEA OF SEQUENTIAL CONSISTENCY (SC)

Arguably the most intuitive memory consistency model is *sequential consistency (SC)*. Sequential consistency was first formalized by Lamport [8]. Lamport first called a single processor (core) *sequential* if “the result of an execution is the same as if the operations had been executed in the order specified by the program.” He then called a multiprocessor *sequentially consistent* if “the result of any execution is the same as if the operations of all processors (cores) were executed in some sequential order, and the operations of each individual processor (core) appear in this sequence in the order specified by its program.” This total order of operations is called *memory order*. In SC, memory order respects each core’s program order, but other consistency models may permit memory orders that do not always respect the program orders.

Figure 3.1 depicts an execution of the example program from Table 3.1. The middle vertical downward arrow represents the memory order ($\langle m \rangle$) while each core’s downward arrow represents its program order ($\langle p \rangle$). We denote memory order using the operator $\langle m \rangle$, so $op1 \langle m \rangle op2$ implies that $op1$ precedes $op2$ in memory order. Similarly, we use the operator $\langle p \rangle$ to denote program order

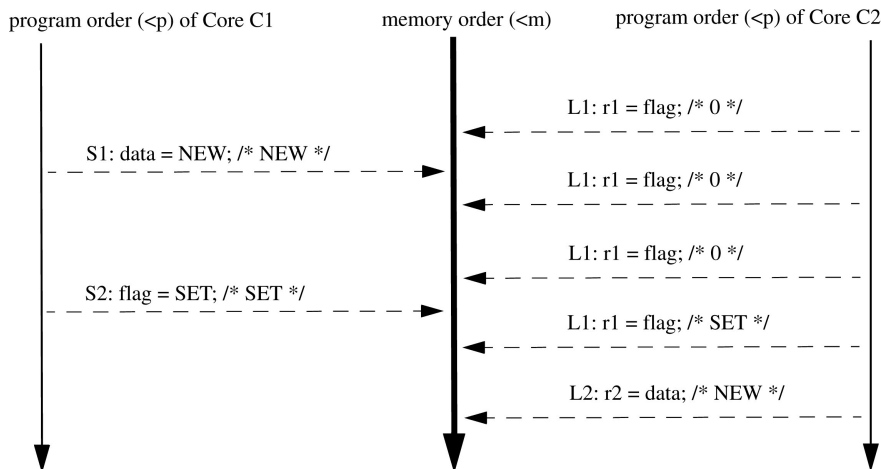

FIGURE 3.1: A Sequentially Consistent Execution of Table 3.1’s Program.

for a given core, so $op1 <_p op2$ implies that $op1$ precedes $op2$ in that core's program order. Under SC, memory order *respects* each core's program order. "Respects" means that $op1 <_p op2$ implies $op1 <_m op2$. The values in comments (*/* ... */*) give the value loaded or stored. This execution terminates with $r2$ being NEW. More generally, all executions of Table 3.1's program terminate with $r2$ as NEW. The only non-determinism—how many times L1 loads flag as 0 before it loads the value SET once—is unimportant.

This example illustrates the value of SC. In Section 3.1, if you expected that $r2$ must be NEW, you were perhaps independently inventing SC, albeit less precisely than Lamport.

The value of SC is further revealed in Figure 3.2, which illustrates four executions of the program from Table 3.3. Figure 3.2(a–c) depict SC executions that correspond to the three intuitive outputs: $(r1, r2) = (0, \text{NEW})$, $(\text{NEW}, 0)$, or (NEW, NEW) . Note that Figure 3.2(c) depicts only one of the four possible SC executions that leads to $(r1, r2) = (\text{NEW}, \text{NEW})$; this execution is $\{S1, S2, L1, L2\}$, and the others are $\{S1, S2, L2, L1\}$, $\{S2, S1, L1, L2\}$, and $\{S2, S1, L2, L1\}$. Thus, across Figure 3.2(a–c), there are six legal SC executions.

Figure 3.2(d) shows a non-SC execution corresponding to the output $(r1, r2) = (0, 0)$. For this output, there is no way to create a memory order that respects program orders. Program order dictates that:

- $S1 <_p L1$
- $S2 <_p L2$

But memory order dictates that:

- $L1 <_m S2$ (so $r1$ is 0)
- $L2 <_m S1$ (so $r2$ is 0)

Honoring all these constraints results in a cycle, which is inconsistent with a total order. The extra arcs in Figure 3.2(d) illustrate the cycle.

We have just seen six SC executions and one non-SC execution. This can help us understand SC implementations: an SC implementation must allow one or more of the first six executions, but cannot allow the seventh execution.

We have also just observed a key distinction between consistency and coherence. Coherence applies on a per-block basis, whereas consistency is defined across all blocks. (Forecasting ahead to Chapter 7, we will see that snooping systems ensure a total order of coherence requests across all blocks, even though coherence requires only a total order of coherence requests to each individual block. This seeming overkill is required for snooping protocols to support consistency models such as SC.)

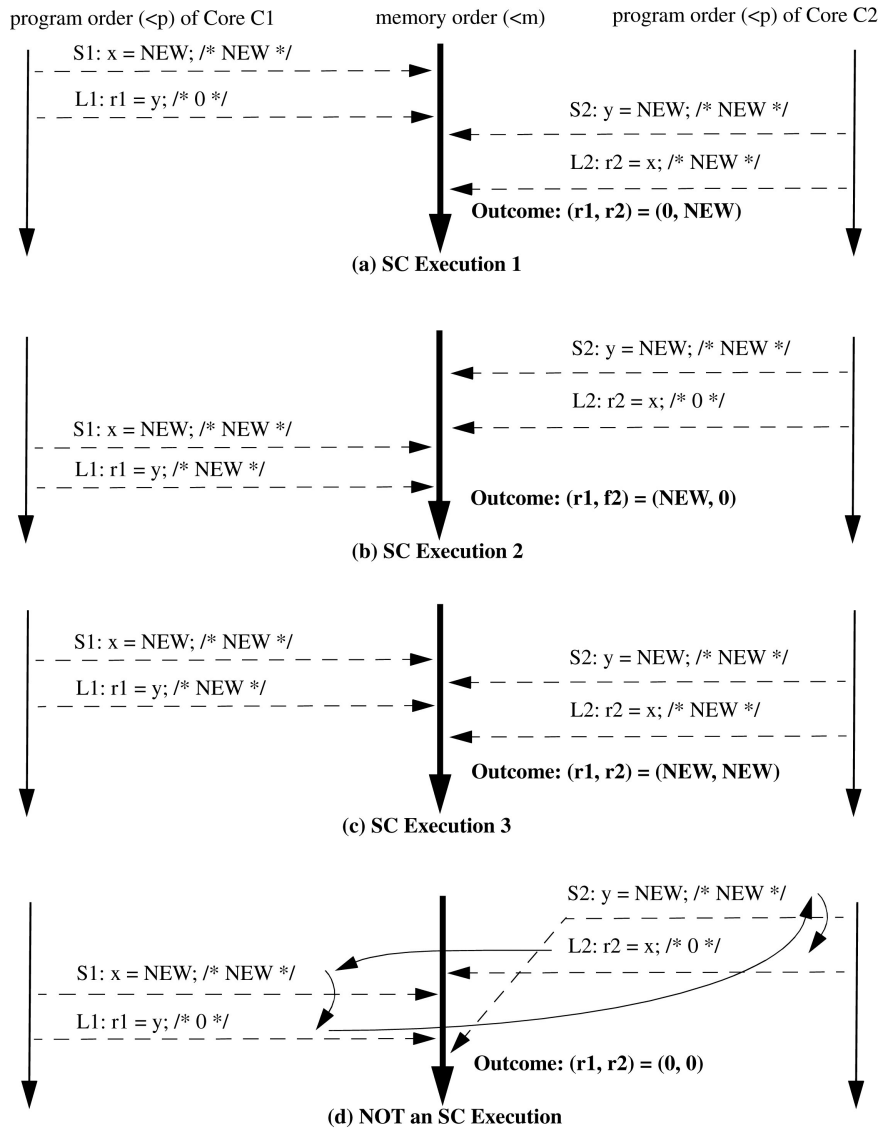

FIGURE 3.2: Four Alternative Executions of Table 3.3’s Program.

3.5 A LITTLE SC FORMALISM

In this section, we define SC more precisely, especially to allow us to compare SC with the weaker consistency models in the next two chapters. We adopt the formalism of Weaver and Germond [17 (Appendix D)] with the following notation: $L(a)$ and $S(a)$ represent a load and a store, respectively, to address a . Orders $\langle p \rangle$ and $\langle m \rangle$ define program and global memory order, respectively. Program order $\langle p \rangle$ is a per-core total order that captures the order in which each core logically (sequentially)

executes memory operations. Global memory order $<_m$ is a total order on the memory operations of all cores.

An **SC execution** requires:

(1) All cores insert their loads and stores into the order $<_m$ respecting their program order, regardless of whether they are to the same or different addresses (i.e., $a=b$ or $a \neq b$). There are four cases:

- If $L(a) <_p L(b) \Rightarrow L(a) <_m L(b)$ /* Load→Load */
- If $L(a) <_p S(b) \Rightarrow L(a) <_m S(b)$ /* Load→Store */
- If $S(a) <_p S(b) \Rightarrow S(a) <_m S(b)$ /* Store→Store */
- If $S(a) <_p L(b) \Rightarrow S(a) <_m L(b)$ /* Store→Load */

(2) Every load gets its value from the last store before it (in global memory order) to the same address:

Value of $L(a) = \text{Value of } \text{MAX}_{<_m} \{S(a) \mid S(a) <_m L(a)\}$, where $\text{MAX}_{<_m}$ denotes “latest in memory order.”

Atomic read–modify–write (RMW) instructions, which we discuss in more depth in Section 3.9, further constrain allowed executions. Each execution of a test-and-set instruction, for example, requires that the load for the test and the store for the set logically appear consecutively in the memory order (i.e., no other memory operations for the same or different addresses interpose between them).

We summarize SC’s ordering requirements in Table 3.4. The table specifies which program orderings are enforced by the consistency model. For example, if a given thread has a load before a store in program order (i.e., the load is “Operation 1” and the store is “Operation 2” in the table),

TABLE 3.4: SC Ordering Rules. An “X” Denotes an Enforced Ordering.

		Operation 2		
		Load	Store	RMW
Operation 1	Load	X	X	X
	Store	X	X	X
	RMW	X	X	X

then the table entry at this intersection is an “X” which denotes that these operations must be performed in program order. For SC, all memory operations must appear to perform in program order; under other consistency models, which we study in the next two chapters, some of these ordering constraints are relaxed (i.e., some entries in their ordering tables do not contain an “X”).

An **SC implementation** permits only SC executions. Strictly speaking, this is the *safety* property for SC implementations (do no harm). SC implementations should also have some *liveness* properties (do some good). At minimum, an SC implementation should permit at least one SC execution for every program. More generally, starvation avoidance and some fairness are also valuable, but these issues are beyond the scope of this discussion.

3.6 NAIVE SC IMPLEMENTATIONS

SC permits two naive implementations that make it easier to understand which executions SC permits.

The Multitasking Uniprocessor

First, one can implement SC for multi-threaded user-level software by executing all threads on a single sequential core (a uniprocessor). Thread T1’s instructions execute on core C1 until a context switch to thread T2, etc. On a context switch, any pending memory operations must be completed before switching to the new thread. An inspection reveals that all SC rules are obeyed.

The Switch

Second, one can implement SC with a set of cores C_i , a single switch, and memory, as depicted in Figure 3.3. Assume that each core presents memory operations to the switch one at a time in its program order. Each core can use any optimizations that do not affect the order in which it presents memory operations to the switch. For example, a simple 5-stage in-order pipeline with branch prediction can be used.

FIGURE 3.3: A Simple SC Implementation Using a Memory Switch.

Assume next that the switch picks one core, allows memory to fully satisfy the load or store, and repeats this process as long as requests exist. The switch may pick cores by any method (e.g., random) that does not starve a core with a ready request. This implementation operationally implements SC by construction.

Assessment

The good news from these implementations is that they provide operational models defining (1) allowed SC executions and (2) SC implementation “gold standards.” The switch implementation also serves as an existence proof that SC can be implemented without caches or coherence.

The bad news, of course, is that the performance of these implementations does not scale up with increasing core count, due to the sequential bottleneck of using a single core in the first case and the single switch/memory in the second case. These bottlenecks have led some people to incorrectly conclude that SC precludes true parallel execution. It does not, as we will see next.

3.7 A BASIC SC IMPLEMENTATION WITH CACHE COHERENCE

Cache coherence facilitates SC implementations that can execute *non-conflicting* loads and stores—two operations *conflict* if they are to the same address and at least one of them is a store—completely in parallel. Moreover, creating such a system is conceptually simple.

Here, we treat coherence as mostly a black box that implements the Single-Writer–Multiple Reader (SWMR) invariant of Chapter 2. We provide some implementation intuition by opening the coherence block box slightly to reveal simple level-one (L1) caches that:

- use state *modified* (*M*) to denote an L1 block that one core can write and read,
- use state *shared* (*S*) to denote an L1 block that one or more cores can only read, and
- have *GetM* and *GetS* denote coherence requests to obtain a block in *M* and *S*, respectively.

We do not require a deep understanding of how coherence is implemented, as discussed in Chapter 6 and beyond.

Figure 3.4(a) depicts the model of Figure 3.3 with the switch and memory replaced by a cache-coherent memory system represented as a black box. Each core presents memory operations to the cache-coherent memory system one at a time in its program order. The memory system fully satisfies each request before beginning the next request for the same core.

Figure 3.4(b) “opens” the memory system black box a little to reveal that each core connects to its own L1 cache (we will talk about multithreading later). The memory system can respond to a load or store to block B if it has B with appropriate coherence permissions (state *M* or *S*

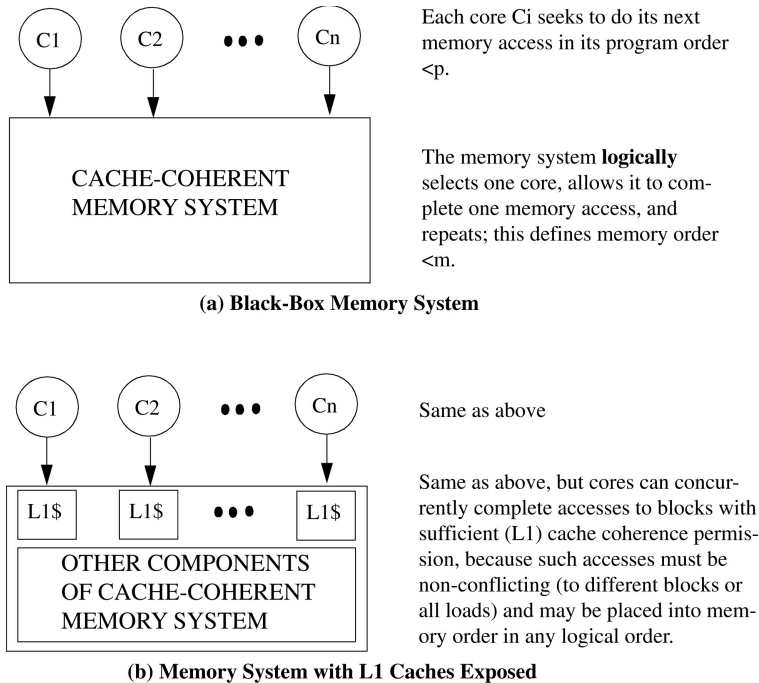

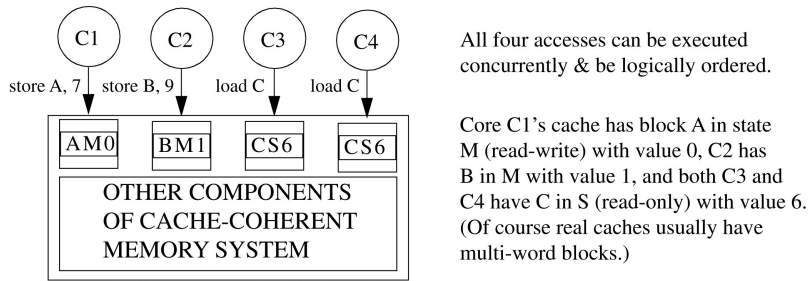

FIGURE 3.4: Implementing SC with Cache Coherence.

for loads and M for stores). Moreover, the memory system can respond to requests from different cores in parallel, provided that the corresponding L1 caches have the appropriate permissions. For example, Figure 3.5(a) depicts the cache states before four cores each seek to do a memory operation. The four operations do not conflict, can be satisfied by their respective L1 caches, and therefore can be done concurrently. As depicted in Figure 3.5(b), we can arbitrarily order these operations to obtain a legal SC execution model. More generally, operations that can be satisfied by L1 caches always can be done concurrently because coherence’s single-writer–multiple-reader invariant ensures they are non-conflicting.

Assessment

We have created an implementation of SC that:

- fully exploits the latency and bandwidth benefits of caches,
- is as scalable as the cache coherence protocol it uses, and
- decouples the complexities of implementing cores from implementing coherence.

(a) Four Accesses Executed Concurrently

(b) Four Accesses Logically Ordered in an SC Execution (one possible ordering)

FIGURE 3.5: A Concurrent SC Execution with Cache Coherence.

3.8 OPTIMIZED SC IMPLEMENTATIONS WITH CACHE COHERENCE

Most real core implementations are more complicated than our basic SC implementation with cache coherence. Cores employ features like prefetching, speculative execution, and multithreading in order to improve performance and tolerate memory access latencies. These features interact with the memory interface, and we now discuss how these features impact the implementation of SC.

Non-Binding Prefetching

A non-binding prefetch for block B is a request to the coherent memory system to change B's coherence state in one or more caches. Most commonly, prefetches are requested by software, core hardware, or the cache hardware to change B's state in the level-one cache to permit loads (e.g., B's state is M or S) or loads and stores (B's state is M) by issuing coherence requests such as GetS and GetM. Importantly, in no case does a non-binding prefetch change the state of a register or data in block B. The effect of the non-binding prefetch is limited to within the "cache-coherent memory system" block of Figure 3.4, making the effect of non-binding prefetches on the memory

consistency model to be the functional equivalent of a no-op. So long as the loads and stores are performed in program order, it does not matter in what order coherence permissions are obtained.

Implementations may do non-binding prefetches without affecting the memory consistency model. This is useful for both internal cache prefetching (e.g., stream buffers) and more aggressive cores.

Speculative Cores

Consider a core that executes instructions in program order, but also does branch prediction wherein subsequent instructions, including loads and stores, begin execution, but may be squashed (i.e., have their effects nullified) on a branch misprediction. These squashed loads and stores can be made to look like non-binding prefetches, enabling this speculation to be correct because it has no effect on SC. A load after a branch prediction can be presented to the L1 cache, wherein it either misses (causing a non-binding GetS prefetch) or hits and then returns a value to a register. If the load is squashed, the core discards the register update, erasing any functional effect from the load—as if it never happened. The cache does not undo non-binding prefetches, as doing so is not necessary and prefetching the block can help performance if the load gets re-executed. For stores, the core may issue a non-binding GetM prefetch early, but it does not present the store to the cache until the store is guaranteed to commit.

Flashback to Quiz Question 1: In a system that maintains sequential consistency, a core must issue coherence requests in program order. *True or false?*

Answer: *False!* A core may issue coherence requests in any order.

Dynamically Scheduled Cores

Many modern cores dynamically schedule instruction execution out of program order to achieve greater performance than statically scheduled cores that must execute instructions in strict program order. A single-core processor that uses dynamic or out-of-(program-)order scheduling must simply enforce true data dependences within the program. However, in the context of a multicore processor, dynamic scheduling introduces a new issue: memory consistency speculation. Consider a core that wishes to dynamically reorder the execution of two loads, L1 and L2 (e.g., because L2's address is computed before L1's address). Many cores will speculatively execute L2 before L1, and they are predicting that this reordering is not visible to other cores, which would violate SC.

Speculating on SC requires that the core verify that the prediction is correct. Gharachorloo et al. [4] presented two techniques for performing this check. First, after the core speculatively executes L2, but before it commits L2, the core could check that the speculatively accessed block has not left the cache. So long as the block remains in the cache, its value could not have changed

between the load's execution and its commit. To perform this check, the core tracks the address loaded by L2 and compares it to blocks evicted and to incoming coherence requests. An incoming GetM indicates that another core could observe L2 out of order, and this GetM would imply a mis-speculation and squash the speculative execution.

The second checking technique is to replay each speculative load when the core is ready to commit the load² [2, 14]. If the value loaded at commit does not equal the value that was previously loaded speculatively, then the prediction was incorrect. In the example, if the replayed load value of L2 is not the same as the originally loaded value of L2, then the load-load reordering has resulted in an observably different execution and the speculative execution must be squashed.

Non-Binding Prefetching in Dynamically Scheduled Cores

A dynamically scheduled core is likely to encounter load and store misses out of program order. For example, assume that program order is Load A, Store B, then Store C. The core may initiate non-binding prefetches “out of order,” e.g., GetM C first and then GetS A and GetM B in parallel. SC is not affected by the order of non-binding prefetches. SC requires only that a core's loads and stores (appear to) access its level-one cache in program order. Coherence requires the level-one cache blocks to be in the appropriate states to receive loads and stores.

Importantly, SC (or any other memory consistency model):

- dictates the order in which loads and stores (appear to) get applied to coherent memory but
- does NOT dictate the order of coherence activity.

Flashback to Quiz Question 2: The memory consistency model specifies the legal orderings of coherence transactions. *True or false?*

Answer: *False!*

Multithreading

Multithreading—at coarse grain, fine grain, or simultaneous—can be accommodated by SC implementations. Each multithreaded core should be made logically equivalent to multiple (virtual) cores sharing each level-one cache via a switch where the cache chooses which virtual core to service next. Moreover, each cache can actually serve multiple non-conflicting requests concurrently because it can pretend that they were serviced in some order. One challenge is ensuring that a thread T1 cannot read a value written by another thread T2 on the same core before the store has been made “visible” to threads on other cores. Thus, while thread T1 may read the value as soon as thread T2

²Roth [14] demonstrated a scheme for avoiding many load replays by determining when they are not necessary.

inserts the store in the memory order (e.g., by writing it to a cache block in state M), it cannot read the value from a shared load-store queue in the processor core.

3.9 ATOMIC OPERATIONS WITH SC

To write multithreaded code, a programmer needs to be able to synchronize the threads, and such synchronization often involves atomically performing pairs of operations. This functionality is provided by instructions that atomically perform a “read–modify–write” (RMW), such as the well-known “test-and-set,” “fetch-and-increment,” and “compare-and-swap.” These atomic instructions are critical for proper synchronization and are used to implement spin-locks and other synchronization primitives. For a spin-lock, a programmer might use an RMW to atomically read whether the lock’s value is unlocked (e.g., equal to 0) and write the locked value (e.g., equal to 1). For the RMW to be atomic, the read (load) and write (store) operations of the RMW must appear consecutively in the total order of operations required by SC.

Implementing atomic instructions in the microarchitecture is conceptually straightforward, but naive designs can lead to poor performance for atomic instructions. A correct but simplistic approach to implementing atomic instructions would be for the core to effectively lock the memory system (i.e., prevent other cores from issuing memory accesses) and perform its read, modify, and write operations to memory. This implementation, although correct and intuitive, sacrifices performance.

More aggressive implementations of RMWs leverage the insight that SC requires only the appearance of a total order of all requests. Thus, an atomic RMW can be implemented by first having a core obtain the block in state M in its cache, if the block is not already there in that state. The core then needs to only load and store the block in its cache—without any coherence messages or bus locking—as long as it waits to service any incoming coherence request for the block until after the store. This waiting does not risk deadlock because the store is guaranteed to complete.

Flashback to Quiz Question 3: To perform an atomic read–modify–write instruction (e.g., test-and-set), a core must always communicate with the other cores. *True or false?*

Answer: *False!*

An even more optimized implementation of RMWs could allow more time between when the load part and store part perform, without violating atomicity. Consider the case where the block is in a read-only state in the cache. The load part of the RMW can speculatively perform immediately, while the cache controller issues a coherence request to upgrade the block’s state to read–write. When the block is then obtained in read–write state, the write part of the RMW performs. As long as the core can maintain the illusion of atomicity, this implementation is correct. To check whether

the illusion of atomicity is maintained, the core must check whether the loaded block is evicted from the cache between the load part and the store part; this speculation support is the same as that needed for detecting mis-speculation in SC (Section 3.8).

3.10 PUTTING IT ALL TOGETHER: MIPS R10000

The MIPS R10000 [18] provides a venerable, but clean, commercial example for a speculative microprocessor that implements SC in cooperation with a cache-coherent memory hierarchy. Herein, we concentrate on aspects of the R10000 that pertain to implementing memory consistency.

The R10000 is a four-way superscalar RISC processor core with branch prediction and out-of-order execution. The chip supports writeback caches for L1 instructions and L1 data, as well as a private interface to an (off-chip) unified L2 cache.

The chip's main *system interface bus* supports cache coherence for up to four processors, as depicted in Figure 3.6 (adapted from Figure 1 in Yeager [18]). To construct an R10000-based system with more processors, such as the SGI Origin 2000 (discussed at length in Section 8.8.1), architects implemented a directory coherence protocol that connects R10000 processors via the system interface bus and a specialized Hub chip. In both cases, the R10000 processor core sees a coherent memory system that happens to be partially on-chip and partially off-chip.

During execution, an R10000 core issues (speculative) loads and stores in program order into an *address queue*. A load obtains a (speculative) value from the last store before it to the same address or, if none, the data cache. Loads and stores commit in program order and then remove their address queue entries. To commit a store, the L1 cache must hold the block in state M and the store's value must be written atomically with the commit.

Importantly, the eviction of a cache block—due to a coherence invalidation or to make room for another block—that contains a load's address in the address queue squashes the load and all subsequent instructions, which then re-execute. Thus, when a load finally commits, the loaded block was continuously in the cache between when it executed and when it commits, so it must get the same value as if it executed at commit. Because stores actually write to the cache at commit,

FIGURE 3.6: Coherent MESI bus connects up to four MIPS R10000 processors.

the R10000 logically presents loads and stores in program order to the coherent memory system, thereby implementing SC, as discussed above.

3.11 FURTHER READING REGARDING SC

Below we highlight a few of the papers from the vast literature surrounding SC.

Lamport [8] defined SC. As far as we know, Meixner and Sorin [11, 12] were the first to prove that a system in which cores present loads and stores in program order to a cache coherent memory system was sufficient to implement SC, even as this result was intuitively believed for some time.

SC can be compared with database serializability [6]. The two concepts are similar in that they both insist that the operations from all entities appear to affect shared state in a serial order. The concepts differ due to the nature of and expectation for operations and shared state. With SC, each operation is a single memory access to volatile state (memory) that is assumed not to fail. With serializability, each operation is a transaction on a database that can read and write multiple database entities and is expected to obey ACID properties: Atomic—all or nothing even with failures, Consistent—leave the database consistent, Isolated—no effect from concurrent transactions, and Durable—effects survive crashes and power loss.

We followed Lamport and SPARC to define a total order of all memory accesses. While this can ease intuition for some, it is not necessary. Let two accesses *conflict* if they are from different threads, access the same location, and at least one is a store (or read–modify–write). Instead of a total order, one can just define the constraints on conflicting accesses and leave non-conflicting accesses unordered, as pioneered by Shasha and Snir [15]. This view can be especially valuable for the relaxed models of Chapter 5.

There have been many papers on aggressive implementations of SC. Gharachorloo et al. [4] show that non-binding prefetches and speculative execution are permitted when implementing SC and other memory models. Ranganathan et al. [13] and Gniady et al. [5] seek to speculatively retire (commit) instructions (freeing resources) and handle SC violations with secondary mechanisms. Recent work has implemented SC by building on implicit transactions and related mechanisms [1, 3, 7, 16].

Finally, a cautionary tale. We stated earlier (Section 3.7) that one way to check whether a speculatively executed load could have been observed out of order is to remember the value *A* that is speculatively read by a load and to commit the load if, at commit, the memory location has the same value *A*. Martin et al. [10] show that this is *not* the case for cores that perform value prediction [9]. With value prediction, when a load executes, the core can speculate on its value. Consider a core that speculates that a load of block *X* will produce the value *A*, although the value is actually *B*. Between when the core speculates on the load of *X* and when it replays the load at commit,

another core changes block X's value to A. The core then replays the load at commit, compares the two values, which are equal, and mistakenly determines that the speculation was correct. The system can violate SC if it speculates in this way. This situation is analogous to the so-called ABA problem [http://en.wikipedia.org/wiki/ABA_problem], and Martin et al. showed that there are ways of checking speculation in the presence of value prediction that avoid the possibility of consistency violations (e.g., by also replaying all loads dependent on the initially speculated load). The point of this discussion is not to delve into the details of this particular corner case or its solutions, but rather to convince you to prove that your implementation is correct rather than rely on intuition.

CHAPTER 4

Total Store Order and the x86 Memory Model

A widely implemented memory consistency model is *total store order (TSO)*. TSO is used in SPARC implementations and, more importantly, appears to match the memory consistency model of the widely used x86 architecture. This chapter presents this important consistency model using a pattern similar to that in the previous chapter on sequential consistency. We first motivate TSO/x86 (Section 4.1) in part by pointing out limitations of SC. We then present TSO/x86 at an intuitive level (Section 4.1) before describing it more formally (Section 4.3), explaining how systems implement TSO/x86 (Section 4.4), and discussing how systems with TSO/x86 implement atomic instructions and instructions used to enforce ordering between instructions (Section 4.5). We conclude by discussing other resources for learning more about TSO/x86 (Section 4.6) and comparing TSO/x86 and SC (Section 4.7).

4.1 MOTIVATION FOR TSO/x86

Processor cores have long used *write (store) buffers* to hold committed (retired) stores until the rest of the memory system could process the stores. A store enters the write buffer when the store commits, and a store exits the write buffer when the block to be written is in the cache in a read–write coherence state. Significantly, a store can enter the write buffer before the cache has obtained read–write coherence permissions for the block to be written; the write buffer thus hides the latency of servicing a store miss. Because stores are common, being able to avoid stalling on most of them is an important benefit. Moreover, it seems sensible to not stall the core because the core does not need anything, as the store seeks to update memory but not core state.

For a single-core processor, a write buffer can be made architecturally invisible by ensuring that a load to address *A* returns the value of the most recent store to *A* even if one or more stores to *A* are in the write buffer. This is typically done by either *bypassing* the value of the most recent store to *A* to the load from *A*, where “most recent” is determined by program order, or by stalling a load of *A* if a store to *A* is in the write buffer.

TABLE 4.1: Can Both r1 and r2 be Set to 0?

Core C1	Core C2	Comments
S1: x = NEW; L1: r1 = y;	S2: y = NEW; L2: r2 = x;	/* Initially, x = 0 & y = 0*/

When building a multicore processor, it seems natural to use multiple cores, each with its own bypassing write buffer, and assume that the write buffers continue to be architecturally invisible.

This assumption is wrong. Consider the example code in Table 4.1 (which is the same as Table 3.3 in the previous chapter). Assume a multicore processor with in-order cores, where each core has a single-entry write buffer and executes the code in the following sequence:

- Core C1 executes store S1, but buffers the newly stored NEW value in its write buffer.
- Likewise, core C2 executes store S2 and holds the newly stored NEW value in its write buffer.
- Next, both cores perform their respective loads, L1 and L2, and obtain the old values of 0.
- Finally, both cores' write buffers update memory with the newly stored values NEW.

The net result is that $(r1, r2) = (0, 0)$. As we saw in the previous chapter, this is an execution result forbidden by SC. Without write buffers, the hardware is SC, but with write buffers, it is not, making write buffers architecturally visible in a multicore processor.

One response to write buffers being visible would be to turn them off, but vendors have been loath to do this because of the potential performance impact. Another option is to use aggressive, speculative SC implementations that make write buffers invisible again, but doing so adds complexity and can waste power to both detect violations and handle mis-speculations.

The option chosen by SPARC and later x86 was to abandon SC in favor of a memory consistency model that allows straightforward use of a first-in-first-out (FIFO) write buffer at each core. The new model, TSO, allows the outcome $(r1, r2) = (0, 0)$. This model astonishes some people but, it turns out, behaves like SC for most programming idioms and is well defined in all cases.

4.2 BASIC IDEA OF TSO/x86

As execution proceeds, SC requires that each core preserves the program order of its loads and stores for all four combinations of consecutive operations:

TABLE 4.2: Should r2 Always be Set to NEW?		
Core C1	Core C2	Comments
S1: Store data = NEW; S2: Store flag = SET;	L1: Load r1 = flag; B1: if (r1 ≠ SET) goto L1; L2: Load r2 = data;	/* Initially, data = 0 & flag ≠ SET */ /* L1 & B1 may repeat many times */

- Load → Load
- Load → Store
- Store → Store
- Store → Load /* Included for SC but omitted for TSO */

TSO includes the first three constraints but not the fourth. This omission does not matter for most programs. Table 4.2 repeats the example program of Table 3.1 in the previous chapter. In this case, TSO allows the same executions as SC because TSO preserves the order of core C1’s two stores and core C2’s two (or more) loads. Figure 4.1 (the same as Figure 3.1 in the previous chapter) illustrates the execution of this program.

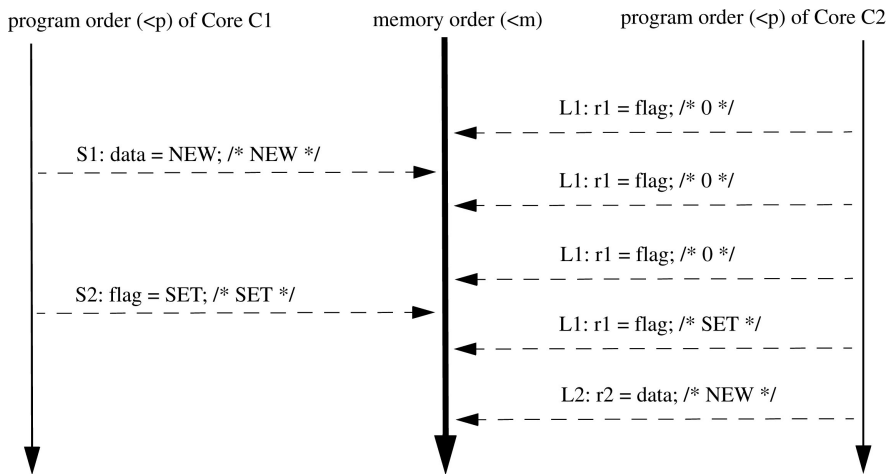

FIGURE 4.1: A TSO Execution of Table 4.2’s Program.

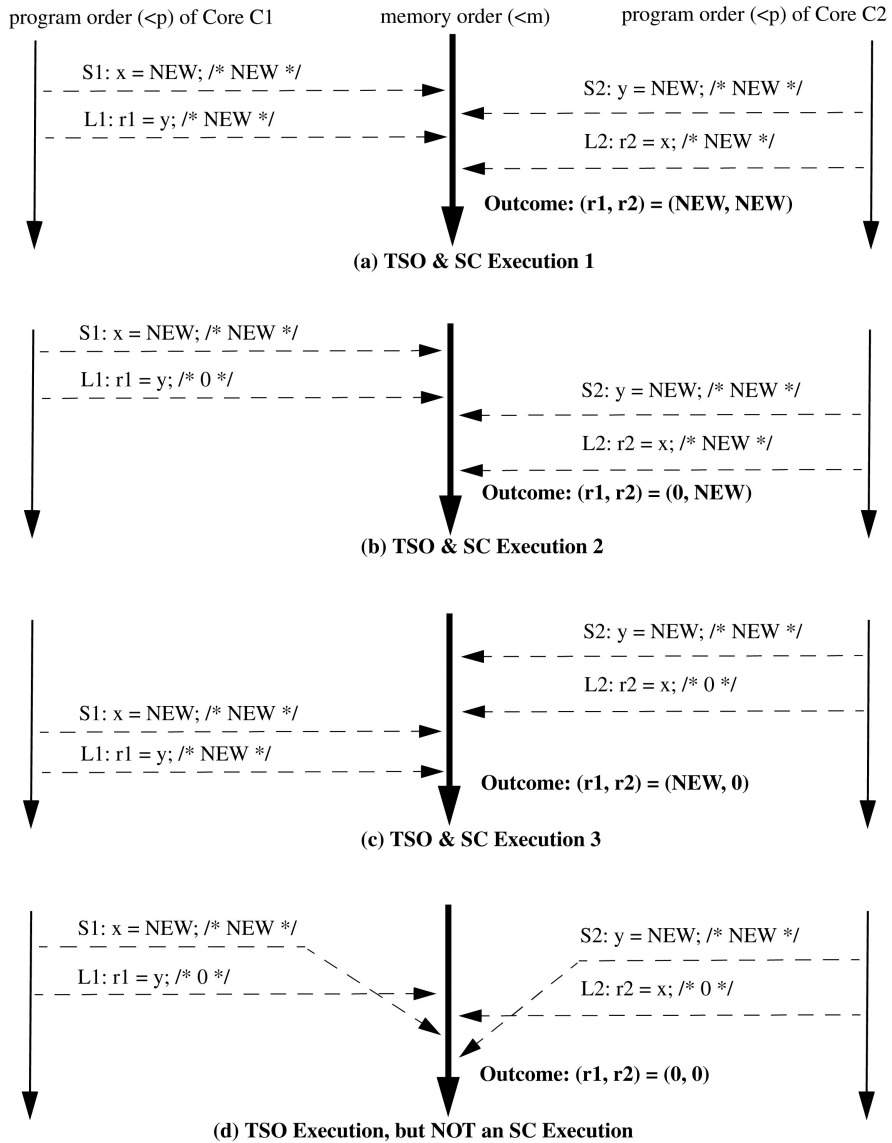

FIGURE 4.2: Four Alternative TSO Executions of Table 4.1's Program.

More generally, TSO behaves the same as SC for common programming idioms that follow:

- C1 loads and stores to memory locations $D1, \dots, Dn$ (often data),
- C1 stores to F (often a synchronization flag) to indicate that the above work is complete,
- C2 loads from F to observe the above work is complete (sometimes spinning first and often using a read–modify–write instruction), and
- C2 loads and stores to some or all of the memory locations $D1, \dots, Dn$.

TSO, however, allows some non-SC executions. Under TSO, the program from Table 4.2 (repeat of Table 3.1 from the last chapter) allows all four outcomes depicted in Figure 4.2. Under SC, only the first three are legal outcomes (as depicted in Figure 3.2 of the last chapter). The execution in Figure 4.2(d) illustrates an execution that conforms to TSO but violates SC by not honoring the fourth (i.e., Store \rightarrow Load) constraint. Omitting the fourth constraint allows each core to use a write buffer. Note that the third constraint means that the write buffer must be FIFO (and not, for example, coalescing) to preserve store–store order.

Programmers (or compilers) can prevent the execution in Figure 4.2(d) by inserting a FENCE instruction between S1 and L1 on core C1 and between S2 and L2 on core C2. Executing a FENCE on core C_i ensures that C_i 's memory operations before the FENCE (in program order) get placed in memory order before C_i 's memory operations after the FENCE. FENCES (a.k.a. memory barriers) are rarely used by programmers using TSO because TSO “does the right thing” for most programs. Nevertheless, FENCES play an important role for the relaxed models discussed in the next chapter.

TSO does allow some non-intuitive execution results. Table 4.3 illustrates a modified version of the program in Table 4.1 in which cores C1 and C2 make local copies of x and y , respectively. Many programmers might assume that if both $r2$ and $r4$ equal 0, then $r1$ and $r3$ should also be 0 because the stores S1 and S2 must be inserted into memory order after the loads L2 and L4. However,

TABLE 4.3: Can $r1$ or $r3$ be Set to 0?

Core C1	Core C2	Comments
S1: $x = \text{NEW};$ L1: $r1 = x;$ L2: $r2 = y;$	S2: $y = \text{NEW};$ L3: $r3 = y;$ L4: $r4 = x;$	/* Initially, $x = 0$ & $y = 0$ */ /* Assume $r2 = 0$ & $r4 = 0$ */

FIGURE 4.3: A TSO Execution of Table 4-3’s Program (with “bypassing”).

Figure 4.3 illustrates an execution that shows r1 and r3 bypassing the value NEW from the per-core write buffers. In fact, to preserve single-thread sequential semantics, each core must see the effect of its own store in program order, even though the store is not yet observed by other cores. Thus, under all TSO executions, the local copies r1 and r3 will always be set to the NEW value.

4.3 A LITTLE TSO FORMALISM AND AN x86 CONJECTURE

In this section we define TSO more precisely with a definition that makes only three changes to the SC definition of Section 3.5.

A **TSO execution** requires:

(1) All cores insert their loads and stores into the memory order <m> respecting their program order, regardless of whether they are to the same or different addresses (i.e., a==b or a!=b). There are four cases:

- If L(a) <p L(b) ⇒ L(a) <m L(b) /* Load → Load */
- If L(a) <p S(b) ⇒ L(a) <m S(b) /* Load → Store */
- If S(a) <p S(b) ⇒ S(a) <m S(b) /* Store → Store */
- **If S(a) <p L(b) ⇒ S(a) <m L(b) /* Store → Load */ /* Change 1: Enable FIFO Write Buffer */**

(2) Every load gets its value from the last store before it to the same address:

$$\text{Value of } L(a) = \text{Value of } \text{MAX}_{<m>} \{S(a) \mid S(a) <m L(a)\} \text{ /* Change 2: Need Bypassing */}$$

$$\text{Value of } L(a) = \text{Value of } \text{MAX}_{<p>} \{S(a) \mid S(a) <p L(a)\}$$

This last mind-bending equation says that the value of a load is the value of the last store to the same address that is either (a) before it in memory order or (b) before it in program order (but

possibly after it in memory order), with option (b) taking precedence (i.e., write buffer bypassing overrides the rest of the memory system).

(3) Part (1) must be augmented to define FENCES: /* Change 4: FENCES Order Everything */

- If $L(a) <_p \text{FENCE} \Rightarrow L(a) <_m \text{FENCE}$ /* Load \rightarrow FENCE */
- If $S(a) <_p \text{FENCE} \Rightarrow S(a) <_m \text{FENCE}$ /* Store \rightarrow FENCE */
- If $\text{FENCE} <_p \text{FENCE} \Rightarrow \text{FENCE} <_m \text{FENCE}$ /* FENCE \rightarrow FENCE */
- If $\text{FENCE} <_p L(a) \Rightarrow \text{FENCE} <_m L(a)$ /* FENCE \rightarrow Load */
- If $\text{FENCE} <_p S(a) \Rightarrow \text{FENCE} <_m S(a)$ /* FENCE \rightarrow Store */

Because TSO already requires all but the Store \rightarrow Load order, one can alternatively define TSO FENCES as only ordering:

- If $S(a) <_p \text{FENCE} \Rightarrow S(a) <_m \text{FENCE}$ /* Store \rightarrow FENCE */
- If $\text{FENCE} <_p L(a) \Rightarrow \text{FENCE} <_m L(a)$ /* FENCE \rightarrow Load */

We choose to have TSO FENCES redundantly order everything because doing so does not hurt and makes them like the FENCES we define for more relaxed models in the next chapter.

We summarize TSO’s ordering rules in Table 4.4. This table has two important differences from the analogous table for SC (Table 3.4). First, if Operation #1 is a store and Operation #2 is

TABLE 4.4: TSO Ordering Rules. An “X” Denotes an Enforced Ordering. A “B” Denotes that Bypassing is Required if the Operations are to the Same Address. Entries that are Different from the SC Ordering Rules are Shaded and Shown in Bold.

		Operation 2			
		Load	Store	RMW	FENCE
Operation 1	Load	X	X	X	X
	Store	B	X	X	X
	RMW	X	X	X	X
	FENCE	X	X	X	X

a load, the entry at that intersection is a “B” instead of an “X”; if these operations are to the same address, the load must obtain the value just stored even if the operations enter memory order out of program order. Second, the table includes FENCES, which were not necessary in SC; an SC system behaves as if there is already a FENCE before and after every operation.

We conjecture that the x86 memory model is equivalent to TSO (for normal cacheable memory and normal instructions). AMD and Intel publicly define the x86 memory model with examples and prose in a process that is well summarized in Section 2 of Sewell et al. [7]. All examples conform to TSO, and all prose seems consistent with TSO. This equivalence can be proven only if a public, formal description of the x86 memory model were made available. This equivalence could be disproved if counter-example(s) showed an x86 execution not allowed by TSO, a TSO execution not allowed by x86, or both.

Our conjecture is supported by a recent work by Sewell et al. [7], summarized in CACM with more details elsewhere [6, 5]. In particular, the authors propose the x86-TSO model. The model has two forms that the authors prove equivalent. The first form provides an abstract machine that resembles Figure 4.4(a) of the next section with the addition of a single global lock for modeling

(a) A TSO Implementation Using a Switch

This implementation is the same as for Figure 3-3, except that each core C_i has a FIFO write buffer that buffers stores until they go to memory.

(b) A TSO Implementation Using Cache Coherence

This TSO implementation replaces the switch above with a cache-coherent memory system in a manner analogous to what was done for SC.

FIGURE 4.4: Two TSO Implementations

x86 LOCK'd instructions. The second form is a labeled transition system. The first form makes the model accessible to practitioners while the latter eases formal proofs. On one hand, x86-TSO appears consistent with the informal rules and litmus tests in x86 specifications. On the other hand, empirical tests on several AMD and Intel platforms did not reveal any violations of the x86-TSO model (but this is no proof that they cannot). In summary, like Sewell et al., we urge creators of x86 hardware and software to adopt the unambiguous and accessible x86-TSO model.

4.4 IMPLEMENTING TSO/x86

The implementation story for TSO/x86 is similar to SC with the addition of per-core FIFO write buffers. Figure 4.4(a) updates the switch of Figure 3.3 to accommodate TSO and operates as follows:

- Loads and stores leave each core in that core's program order $\langle p$.
- A load either bypasses a value from the write buffer or awaits the switch as before.
- A store enters the tail of the FIFO write buffer or stalls the core if the buffer is full.
- When the switch selects core C_i , it performs either the next load or the store at the head of the write buffer.

In Section 3.7, we showed that, for SC, the switch can be replaced by a cache coherent memory system and then argued that cores could be speculative and/or multithreaded and that non-binding prefetches could be initiated by cores, caches, or software.

As illustrated in Figure 4.4(b), the *same* argument holds for TSO with a FIFO writer buffer interposed between each core and the cache-coherent memory system. Thus, aside from the write buffer, all the previous SC implementation discussion holds for TSO and provides a way to build TSO implementations. Moreover, most current TSO implementations seem to use only the above approach: take an SC implementation and insert write buffers. For this reason, this TSO implementation section is short.

Regarding the write buffer, the literature and product space for how exactly speculative cores implement them is beyond the scope of this chapter. For example, microarchitectures can physically combine the store queue (uncommitted stores) and write buffer (committed stores), and/or physically separate load and store queues.

Finally, multithreading introduces a subtle write buffer issue for TSO. TSO write buffers are logically private to each thread context (virtual core). Thus, on a multithreaded core, one thread context should never bypass from the write buffer of another thread context. This logical separation can be implemented with per-thread-context write buffers or, more commonly, by using a shared

write buffer with entries tagged by thread-context identifiers that permit bypassing only when tags match.

Flashback to Quiz Question 4: In a TSO system with multithreaded cores, threads may bypass values out of the write buffer, regardless of which thread wrote the value. *True or false?*

Answer: *False!* A thread may bypass values that it has written, but other threads may not see the value until the store is inserted into the memory order.

4.5 ATOMIC INSTRUCTIONS AND FENCES WITH TSO

Systems that implement TSO must provide atomic instructions, like systems that implement SC, as well as FENCE instructions. In this section, we discuss how to implement atomic instructions and FENCES for systems that support TSO.

4.5.1 Atomic Instructions

The implementation issues for atomic RMW instructions in TSO are similar to those for atomic instructions for SC. The key difference is that TSO allows loads to pass (i.e., be ordered before) earlier stores that have been written to a write buffer. The impact on RMWs is that the “write” (i.e., store) may be written to the write buffer.

To understand the implementation of atomic RMWs in TSO, we consider the RMW as a load immediately followed by a store. The load part of the RMW cannot pass earlier loads due to TSO’s ordering rules. It might at first appear that the load part of the RMW could pass earlier stores in the write buffer, but this is not legal. If the load part of the RMW passes an earlier store, then the store part of the RMW would also have to pass the earlier store because the RMW is an atomic pair. But because stores are not allowed to pass each other in TSO, the load part of the RMW cannot pass an earlier store either.

These ordering constraints on RMWs impact the implementation. Because the load part of the RMW cannot be performed until earlier stores have been ordered (i.e., exited the write buffer), the atomic RMW effectively drains the write buffer before it can perform the load part of the RMW. Furthermore, to ensure that the store part can be ordered immediately after the load part, the load part requires read–write coherence permissions, not just the read permissions that suffice for normal loads. Lastly, to guarantee atomicity for the RMW, the cache controller may not relinquish coherence permission to the block between the load and the store.

More optimized implementations of RMWs are possible. For example, the write buffer does not need to be drained as long as (a) every entry already in the write buffer has read–write permission in the cache and maintains the read–write permission in the cache until the RMW commits,

TABLE 4.5: Can Both r1 and r2 be Set to 0?

Core C1	Core C2	Comments
S1: x = NEW; FENCE L1: r1 = y;	S2: y = NEW; FENCE L2: r2 = x;	/* Initially, x = 0 & y = 0*/

and (b) the core performs MIPS R10000-style checking of load speculation (Section 3.8). Logically, all of the earlier stores and loads would then commit as a unit (sometimes called a “chunk”) immediately before the RMW.

4.5.2 FENCES

Systems that support TSO do not provide ordering between a store and a subsequent (in program order) load, although they do require the load to get the value of the earlier store. In situations in which the programmer wants those instructions to be ordered, the programmer must explicitly specify that ordering by putting a FENCE instruction between the store and the subsequent load. The semantics of the FENCE specify that all instructions before the FENCE in program order must be ordered before any instructions after the FENCE in program order. For systems that support TSO, the FENCE thus prohibits a load from bypassing an earlier store. In Table 4.5, we revisit the example from Table 4.1, but we have added two FENCE instructions that were not present earlier. Without these FENCES, the two loads (L1 and L2) can bypass the two stores (S1 and S2), leading to an execution in which r1 and r2 both get set to zero. The added FENCES prohibit that reordering and thus prohibit that execution.

Because TSO permits only one type of reordering, FENCES are fairly infrequent and the implementation of FENCE instructions is not too critical. A simple implementation—such as draining the write buffer when a FENCE is executed and not permitting subsequent loads to execute until an earlier FENCE has committed—may provide acceptable performance. However, for consistency models that permit far more reordering (discussed in the next chapter), FENCE instructions are more frequent and their implementations can have a significant impact on performance.

4.6 FURTHER READING REGARDING TSO

Collier [2] characterized alternative memory consistency models, including that of the IBM System/370, via a model in which each core has a full copy of memory, its loads read from the local

copy, and its writes update all copies according to some restrictions that define a model. Were TSO defined with this model, each store would write its own core's memory copy immediately and then possibly later update all other memories together.

Goodman [4] publicly discussed the idea of *processor consistency (PC)*, wherein a core's stores reach other cores in order but do not necessarily reach other cores at the same "time." Gharachorloo et al. [3] more precisely define PC. TSO and x86 are a special case of PC in which each core sees its own store immediately, and when any other cores see a store, all other cores see it. This property is called *write atomicity* in the next chapter (Section 5.5).

To the best of our knowledge, TSO was first formally defined by Sindhu et al. [8]. As discussed, in Section 4.3, Sewell et al. [6, 5, 7] propose and formalize the x86-TSO model that appears consistent with AMD and Intel x86 documentation and current implementations.

4.7 COMPARING SC AND TSO

Now that we have seen two memory consistency models, we can compare them. How do SC, TSO, etc., relate?

- *Executions:* SC executions are a proper subset of TSO executions; all SC executions are TSO executions, while some TSO executions are SC executions and some are not. See the Venn diagram in Figure 4.5(a).
- *Implementations:* Implementations follow the same rules: SC implementations are a proper subset of TSO implementations. See Figure 4.5(b), which is the same as Figure 4.5(a).

More generally, a memory consistency model Y is strictly more *relaxed (weaker)* than a memory consistency model X if all X executions are also Y executions, but not vice versa. If Y is more relaxed than X, then it follows that all X implementations are also Y implementations. It is also possible that two memory consistency models are incomparable because both allow executions precluded by the other.

FIGURE 4.5: Comparing Memory Consistency Models

As Figure 4.5 depicts, TSO is more relaxed than SC but less relaxed than incomparable models MC1 and MC2. In the next chapter, we will see candidates for MC1 and MC2, including a case study for the IBM Power memory consistency model.

What Is a Good Memory Consistency Model?

A good memory consistency model should possess Sarita Adve's 3Ps [1] plus our fourth P:

- *Programmability*: A good model should make it (relatively) easy to write multithreaded programs. The model should be intuitive to most users, even those who have not read the details. It should be precise, so that experts can push the envelope of what is allowed.
- *Performance*: A good model should facilitate high-performance implementations at reasonable power, cost, etc. It should give implementors broad latitude in options.
- *Portability*: A good model would be adopted widely or at least provide backward compatibility or the ability to translate among models.
- *Precision*: A good model should be precisely defined, usually with mathematics. Natural languages are too ambiguous to enable experts to push the envelope of what is allowed.

How Good Are SC and TSO?

Using these 4Ps:

- *Programmability*: SC is the most intuitive. TSO is close because it acts like SC for common programming idioms. Nevertheless, subtle non-SC executions can bite programmers and tool authors.
- *Performance*: For simple cores, TSO can offer better performance than SC, but the difference can be made small with speculation.
- *Portability*: SC is widely understood, while TSO is widely adopted.
- *Precise*: SC, TSO, and x86-TSO are formally defined.

The bottom line is that SC and TSO are pretty close, especially compared with the more complex and more relaxed memory consistency models discussed in the next chapter.

. . . .

CHAPTER 5

Relaxed Memory Consistency

The previous two chapters explored the memory consistency models *sequential consistency (SC)* and *total store order (TSO)*. These chapters presented SC as intuitive and TSO as widely implemented (e.g., in x86). Both models are sometimes called *strong* because the global memory order of each model usually respects (preserves) per-thread program order. Recall that SC preserves order for two memory operations from the same thread for all four combinations of loads and stores (Load \rightarrow Load, Load \rightarrow Store, Store \rightarrow Store, and Store \rightarrow Load), whereas TSO preserves the first three orders but not Store \rightarrow Load order.

This chapter examines more *relaxed (weak) memory consistency models* that seek to preserve only the orders that programmers “require.” The principal benefit of this approach is that mandating fewer ordering constraints can facilitate higher performance by allowing more hardware and software (compiler and runtime system) optimizations. The principal drawbacks are that relaxed models must formalize when ordering is “required” and provide mechanisms for programmers or low-level software to communicate such ordering to implementations, and vendors have failed to agree on a single relaxed model, compromising portability.

A full exploration of relaxed consistency models is beyond the scope of this chapter. This chapter is instead a primer that seeks to provide the basic intuition and help make the reader aware of the limits of a simple understanding of these models. In particular, we provide motivation for relaxed models (Section 5.1), present and formalize an example relaxed consistency model XC (Section 5.2), discuss the implementation of XC, including atomic instructions and instructions used to enforce ordering (Section 5.3), introduce sequential consistency for data-race-free programs (Section 5.4), present additional relaxed model concepts (Section 5.5), present an IBM Power memory model case study (Section 5.6), point to further reading and other commercial models (Section 5.7), compare models (Section 5.8), and touch upon high-level-language memory models (Section 5.9).

5.1 MOTIVATION

As we will soon see, mastering relaxed consistency models can be more challenging than understanding SC and TSO. These drawbacks beg the question: why bother with relaxed models at all?

In this section, we motivate relaxed models, first by showing some common situations in which programmers do not care about instruction ordering (Section 5.1.1) and then by discussing a few of the optimizations that can be exploited when unnecessary orderings are not enforced (Section 5.1.2).

5.1.1 Opportunities to Reorder Memory Operations

Consider the example depicted in Table 5.1. Most programmers would expect that r2 will always get the value NEW because S1 is before S3 and S3 is before the dynamic instance of L1 that loads the value SET, which is before L2. We can denote this:

- S1 → S3 → L1 loads SET → L2.

Similarly, most programmers would expect that r3 will always get the value NEW because:

- S2 → S3 → L1 loads SET → L3.

In addition to these two expected orders above, SC and TSO also require the orders S1 → S2 and L2 → L3. Preserving these additional orders may limit implementation optimizations to aid performance, yet these additional orders are not needed by the program for correct operation.

Table 5.2 depicts a more general case of the handoff between two critical sections using the same lock. Assume that hardware supports lock acquire (e.g., with test-and-set doing a read-modify-write and looping until it succeeds) and lock release (e.g., store the value 0). Let core C1 acquire the lock, do critical section 1 with an arbitrary interleaving of loads (L1i) and stores (S1j), and then release the lock. Similarly, let core C2 do critical section 2, including an arbitrary interleaving of loads (L2i) and stores (S2j).

TABLE 5.1: What Order Ensures r2 & r3 Always Get NEW?

Core C1	Core C2	Comments
S1: data1 = NEW; S2: data2 = NEW; S3: flag = SET;	L1: r1 = flag; B1: if (r1 ≠ SET) goto L1; L2: r2 = data1; L3: r3 = data2;	/* Initially, data1 & data2 = 0 & flag ≠ SET */ /* spin loop: L1 & B1 may repeat many times */

TABLE 5.2: What Order Ensures Correct Handoff from Critical Section 1 to 2?

Core C1	Core C2	Comments
A1: acquire(lock) /* Begin Critical Section 1 */ Some loads L1i interleaved with some stores S1j /* End Critical Section 1 */ R1: release(lock)	A2: acquire(lock) /* Begin Critical Section 2 */ Some loads L2i interleaved with some stores S2j /* End Critical Section 2 */ R2: release(lock)	/* Arbitrary interleaving of L1i's & S1j's */ /* Handoff from critical section 1*/ /* To critical section 2*/ /* Arbitrary interleaving of L2i's & S2j's */

Proper operation of the handoff from critical section 1 to critical section 2 depends on the order of these operations:

- All L1i, All S1j → R1 → A2 → All L2i, All S2j,

where commas (“,”) separate operations whose order is not specified.

Proper operation does *not* depend on any ordering of the loads and stores within each critical section—unless the operations are to the same address (in which case ordering is required to maintain sequential processor ordering). That is:

- All L1i and S1j can be in any order with respect to each other, and
- All L2i and S2j can be in any order with respect to each other.

If proper operation does *not* depend on ordering among many loads and stores, perhaps one could obtain higher performance by relaxing the order among them, since loads and stores are typically much more frequent than lock acquires and releases. This is what relaxed or weak models do.

5.1.2 Opportunities to Exploit Reordering

Assume for now a relaxed memory consistency model that allows us to reorder any memory operations unless there is a FENCE between them. This relaxed model forces the programmer to reason

about which operations need to be ordered, which is a drawback, but it also enables many optimizations that can improve performance. We discuss a few common and important optimizations, but a deep treatment of this topic is beyond the scope of this primer.

5.1.2.1 Non-FIFO, Coalescing Write Buffer

Recall that TSO enables the use of a FIFO write buffer, which improves performance by hiding some or all of the latency of committed stores. Although a FIFO write buffer improves performance, an even more optimized design would use a non-FIFO write buffer that permits coalescing of writes (i.e., two stores that are not consecutive in program order can write to the same entry in the write buffer). However, a non-FIFO coalescing write buffer violates TSO because TSO requires stores to appear in program order. Our example relaxed model allows stores to coalesce in a non-FIFO write buffer, so long as the stores have not been separated by a FENCE.

5.1.2.2 Simpler Support for Core Speculation

In systems with strong consistency models, a core may speculatively execute loads out of program order before they are ready to be committed. Recall how the MIPS R10000 core, which supports SC, used such speculation to gain better performance than a naive implementation that did not speculate. The catch, however, is that speculative cores that support SC have to include mechanisms to check whether the speculation is correct, even if mis-speculations are rare [15, 11]. The R10000 checks speculation by comparing the addresses of evicted cache blocks against a list of the addresses that the core has speculatively loaded but not yet committed (i.e., the contents of the core's load queue). This mechanism adds to the cost and complexity of the hardware, it consumes additional power, and it represents another finite resource that may constrain instruction level parallelism. In a system with a relaxed memory consistency model, a core can execute loads out of program order without having to compare the addresses of these loads to the addresses of incoming coherence requests. These loads are not speculative with respect to the relaxed consistency model (although they may be speculative with respect to, say, a branch prediction or earlier stores by the same thread to the same address).

5.1.2.3 Coupling Consistency and Coherence

We previously advocated decoupling consistency and coherence to manage intellectual complexity. Alternatively, relaxed models can provide better performance than strong models by “opening the coherence box.” For example, an implementation might allow a subset of cores to load the new value from a store even as the rest of the cores can still load the old value, temporarily breaking coherence's single-writer–multiple-reader invariant. This situation can occur, for example, when two thread

contexts logically share a per-core write buffer or when two cores share an L1 data cache. However, “opening the coherence box” incurs considerable intellectual and verification complexity, bringing to mind the Greek myth about Pandora’s box. As we will discuss in Section 5.6, IBM Power permits the above optimizations, but first we explore relaxed models with the coherence box sealed tightly.

5.2 AN EXAMPLE RELAXED CONSISTENCY MODEL (XC)

For teaching purposes, this section introduces an *eXample relaxed Consistency model (XC)* that captures the basic idea and some implementation potential of relaxed memory consistency models. XC assumes that a global memory order exists, as is true for the strong models of SC and TSO, as well as the largely defunct relaxed models for Alpha [26] and SPARC Relaxed Memory Order (RMO) [27].

5.2.1 The Basic Idea of the XC Model

XC provides a FENCE instruction so that programmers can indicate when order is needed; otherwise, by default, loads and stores are unordered. Other relaxed consistency models call a FENCE a barrier, a memory barrier, a membar, or a sync. Let core C_i execute some loads and/or stores, X_i , then a FENCE instruction, and then some more loads and/or stores, Y_i . The FENCE ensures that memory order will order all X_i operations before the FENCE, which in turn is before all Y_i operations. A FENCE instruction does not specify an address. Two FENCES by the same core also stay ordered. However, a FENCE does *not* affect the order of memory operations at *other* cores (which is why “fence” may be a better name than “barrier”). Some architectures include multiple FENCE instructions with different ordering properties; for example, an architecture could include a FENCE instruction that enforces all orders except from a store to a subsequent load. In this chapter, however, we consider only FENCES that order all types of operations.

XC’s memory order is guaranteed to respect (preserve) program order for:

- Load → FENCE
- Store → FENCE
- FENCE → FENCE
- FENCE → Load
- FENCE → Store

XC maintains TSO rules for ordering two accesses to the *same* address only:

- Load → Load to same address
- Load → Store to the same address
- Store → Store to the same address

These rules enforce the sequential processor model (i.e., sequential core semantics) and prohibit behaviors that might astonish programmers. For example, the Store \rightarrow Store rule prevents a critical section that performs “A = 1” then “A = 2” from completing strangely with A set to 1. Likewise, the Load \rightarrow Load rule ensures that if B was initially 0 and another thread performs “B = 1,” then the present thread cannot perform “r1 = B” then “r2 = B” with r1 getting 1 and r2 getting 0, as if B’s value went from new to old.

XC ensures that loads immediately see updates due to their own stores (like TSO’s write buffer bypassing). This rule preserves the sequentiality of single threads, also to avoid programmer astonishment.

5.2.2 Examples Using FENCES Under XC

Table 5.3 shows how programmers or low-level software should insert FENCES in the program of Table 5.1 so that it operates correctly under XC. These FENCES ensure:

- S1, S2 \rightarrow F1 \rightarrow S3 \rightarrow L1 loads SET \rightarrow F2 \rightarrow L2, L3.

The F1 FENCE, which orders stores, makes sense to most readers, but some are surprised by the need for the F2 FENCE ordering loads. However, if one allows the loads to execute out of order, they can make it look like in-order stores executed out of order. For example, if execution can proceed as L2, S1, S2, S3, L1, and L3, then L2 can obtain the value 0. This result is especially possible for a program that does not include the B1 control dependence, so that L1 and L2 are consecutive loads to different addresses, wherein reordering seems reasonable, but is not.

	F24: FENCE	

Table 5.4 shows how programmers or low-level software could insert FENCES in the critical section program of Table 5.2 so that it operates correctly under XC. This FENCE insertion policy, in which FENCES surround each lock acquire and lock release, is conservative for illustration purposes; we will later show that some of these FENCES can be removed. In particular, FENCES F13 and F22 ensure a correct handoff between critical sections because:

- All L1i, All S1j → **F13** → R11 → A21 → **F22** → All L2i, All S2j

Next, we formalize XC and then show why the above two examples work.

5.2.3 Formalizing XC

Here, we formalize XC in a manner consistent with the previous two chapters' notation and approach. Once again, let $L(a)$ and $S(a)$ represent a load and a store, respectively, to address a . Orders $\langle p$ and $\langle m$ define per-processor program order and global memory order, respectively. Program order $\langle p$ is a per-processor total order that captures the order in which each core logically (sequentially) executes memory operations. Global memory order $\langle m$ is a total order on the memory operations of all cores.

More formally, an **XC execution** requires the following:

1. All cores insert their loads, stores, and FENCEs into the order $<_m$ respecting:
 - If $L(a) <_p \text{FENCE} \Rightarrow L(a) <_m \text{FENCE}$ /* Load \rightarrow FENCE */
 - If $S(a) <_p \text{FENCE} \Rightarrow S(a) <_m \text{FENCE}$ /* Store \rightarrow FENCE */
 - If $\text{FENCE} <_p \text{FENCE} \Rightarrow \text{FENCE} <_m \text{FENCE}$ /* FENCE \rightarrow FENCE */
 - If $\text{FENCE} <_p L(a) \Rightarrow \text{FENCE} <_m L(a)$ /* FENCE \rightarrow Load */
 - If $\text{FENCE} <_p S(a) \Rightarrow \text{FENCE} <_m S(a)$ /* FENCE \rightarrow Store */
2. All cores insert their loads and stores to the *same* address into the order $<_m$ respecting:
 - If $L(a) <_p L'(a) \Rightarrow L(a) <_m L'(a)$ /* Load \rightarrow Load to same address */
 - If $L(a) <_p S(a) \Rightarrow L(a) <_m S(a)$ /* Load \rightarrow Store to same address */
 - If $S(a) <_p S'(a) \Rightarrow S(a) <_m S'(a)$ /* Store \rightarrow Store to same address */
3. Every load gets its value from the last store before it to the same address:
 Value of $L(a) = \text{Value of } \text{MAX}_{<_m} \{S(a) \mid S(a) <_m L(a) \text{ or } S(a) <_p L(a)\}$ /* Like TSO */

We summarize these ordering rules in Table 5.5. This table differs considerably from the analogous tables for SC and TSO. Visually, the table shows that ordering is enforced only for operations to the same address or if FENCEs are used. Like TSO, if operation 1 is “store C” and operation 2 is “load C,” the store can enter the global order after the load, but the load must already see the newly stored value.

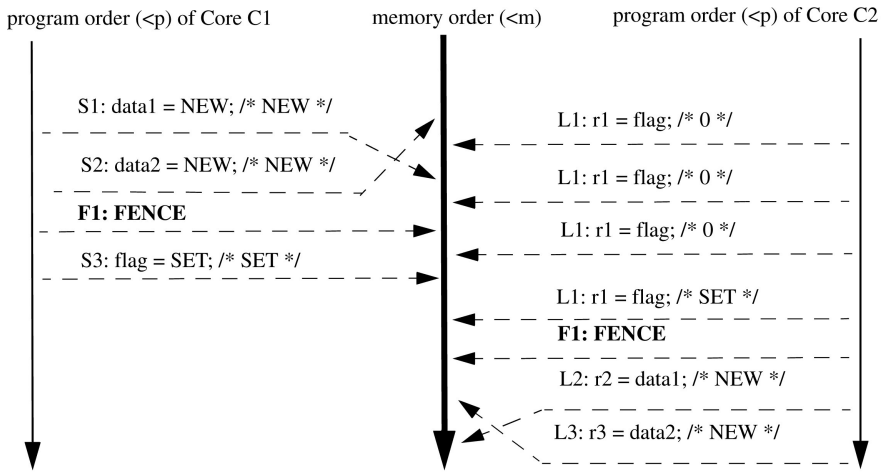

An implementation that allows only XC executions is an **XC implementation**.

TABLE 5.5: XC Ordering Rules. An “X” Denotes an Enforced Ordering. An “A” Denotes an Ordering that is Enforced Only if the Operations are to the Same Address. A “B” Denotes that Bypassing is Required if the Operations are to the Same Address. Entries Different from TSO are Shaded and Indicated in Bold Font.

		Operation 2			
		Load	Store	RMW	FENCE
Operation 1	Load	A	A	A	X
	Store	B	A	A	X
	RMW	A	A	A	X
	FENCE	X	X	X	X

5.2.4 Examples Showing XC Operating Correctly

With the formalisms of the last section, we can now reveal why Section 5.2.2's two examples work correctly. Figure 5.1(a) shows an XC execution of the example from Table 5.3 in which core C1's stores S1 and S2 are reordered, as are core C2's loads L2 and L3. Neither reordering, however, affects the results of the program. Thus, as far as the programmer can tell, this XC execution is equivalent to the SC execution depicted in Figure 5.1(b), in which the two pairs of operations are not reordered.

(a) An XC Execution

(b) An SC Execution

FIGURE 5.1: Two Equivalent Executions of Table 5.3's Program.

Similarly, Figure 5.2(a) depicts an execution of the critical section example from Table 5.4 in which core C1's loads L1i and stores S1j are reordered with respect to each other, as are core C2's L2i and stores S2j. Once again, these reorderings do not affect the results of the program. Thus, as far as the programmer can tell, this XC execution is equivalent to the SC execution depicted in Figure 5.2(b), in which no loads or stores are reordered.

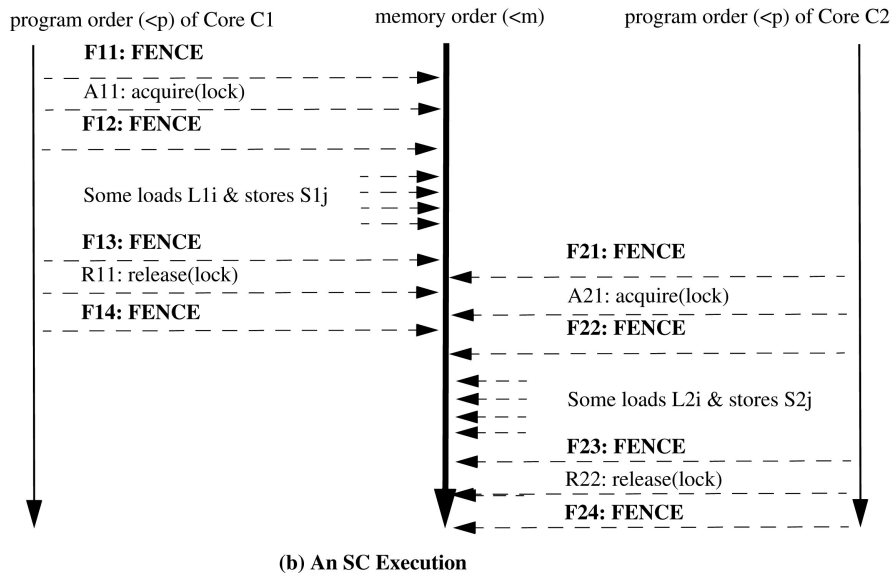

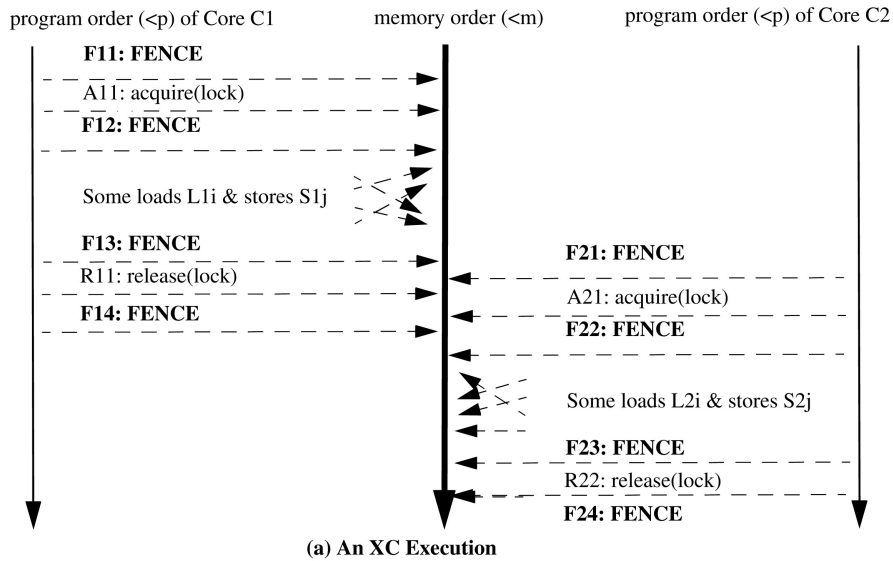

FIGURE 5.2: Two Equivalent Executions of Table 5.4's Critical Section Program.

These examples demonstrate that, with sufficient FENCEs, a relaxed model like XC can appear to programmers as SC. Section 5.4 discusses generalizing from these examples, but first let us implement XC.

5.3 IMPLEMENTING XC

This section discusses implementing XC. We follow an approach similar to that used for implementing SC and TSO in the previous two chapters, in which we separate the reordering of core operations from cache coherence. Recall that each core in a TSO system was separated from shared memory by a FIFO write buffer. For XC, each core will be separated from memory by a more general *reorder unit* that can reorder both loads and stores.

As depicted by Figure 5.3(a), XC operates as follows:

- Loads, stores, and FENCEs leave each core C_i in C_i 's program order $\langle p \rangle$ and enter the *tail* of C_i 's reorder unit.
- C_i 's reorder unit queues operations and passes them from its tail to its *head*, either in program order or reordered within by rules specified below. A FENCE gets discarded when it reaches the reorder unit's head.

(a) An XC Implementation Using a Switch

This XC implementation is modeled after the SC and TSO switch implementations of the previous chapter, except that a more-general *reorder unit* separates cores and the memory switch.

(b) An XC Implementation Using Cache Coherence

This XC implementation replaces the switch above with a cache-coherent memory system in a manner analogous to what was done for SC and TSO in the previous chapters.

FIGURE 5.3: Two XC Implementations.

- When the switch selects core C_i , it performs the load or store at the head of C_i 's reorder unit.

The reorder units obey rules for (1) FENCES, (2) operations to the same address, and (3) bypassing.

1. FENCES can be implemented in several different ways (see Section 5.3.2), but they must enforce order. Specifically, regardless of address, the reorder unit may *not* reorder:

Load \rightarrow FENCE, Store \rightarrow FENCE, FENCE \rightarrow FENCE, FENCE \rightarrow Load, or FENCE \rightarrow Store

2. For the *same* address, the reorder unit may *not* reorder:

Load \rightarrow Load, Load \rightarrow Store, Store \rightarrow Store (to the same address)

3. The reorder unit must ensure that loads immediately see updates due to their own stores.

Not surprisingly, all of these rules mirror those of Section 5.2.3.

In the previous two chapters, we argued that the switch and memory in SC and TSO implementations could be replaced by a cache-coherent memory system. The same argument holds for XC, as illustrated by Figure 5.3(b). Thus, as for SC and TSO, an XC implementation can separate core (re)ordering rules from the implementation of cache coherence. As before, cache coherence implements the global memory order. What is new is that memory order can more often disrespect program order due to reorder unit reorderings.

So how much performance does moving from TSO to a relaxed model like XC afford? Unfortunately, the correct answer depends on the factors discussed in Section 5.1.2, such as FIFO vs. coalescing write buffers and speculation support.

In the late 1990s, one of us saw the trend toward speculative cores as diminishing the *raison d'être* for relaxed models (better performance) and argued for a return to the simpler interfaces of SC or TSO [16]. Although we still believe that simple interfaces are good, the move did not happen. One reason is corporate momentum. Another reason is that not all future cores will be highly speculative due to power-limited deployments in embedded chips and/or chips with many (asymmetric) cores.

5.3.1 Atomic Instructions with XC

There are several viable ways of implementing an atomic RMW instruction in a system that supports XC. The implementation of RMWs also depends on how the system implements XC; in this

section, we assume that the XC system consists of dynamically scheduled cores, each of which is connected to the memory system by a non-FIFO coalescing write buffer.

In this XC system model, a simple and viable solution would be to borrow the implementation we used for TSO. Before executing an atomic instruction, the core drains the write buffer, obtains the block with read–write coherence permissions, and then performs the load part and the store part. Because the block is in a read–write state, the store part performs directly to the cache, bypassing the write buffer. Between when the load part performs and the store part performs, if such a window exists, the cache controller must not evict the block; if an incoming coherence request arrives, it must be deferred until the store part of the RMW performs.

Borrowing the TSO solution for implementing RMWs is simple, but it is overly conservative and sacrifices some performance. Notably, draining the write buffer is not required because XC allows both the load part and the store part of the RMW to pass earlier stores. Thus, it is sufficient to simply obtain read–write coherence permissions to the block and then perform the load part and the store part without relinquishing the block between those two operations.

Other implementations of atomic RMWs are possible, but they are beyond the scope of this primer. One important difference between XC and TSO is how atomic RMWs are used to achieve synchronization. In Table 5.6, we depict a typical critical section, including lock acquire and lock release, for both TSO and XC. With TSO, the atomic RMW is used to attempt to acquire the lock, and a store is used to release the lock. With XC, the situation is more complicated. For the acquire, XC does not, by default, constrain the RMW from being reordered with respect to the operations in the critical section. To avoid this situation, a lock acquire must be followed by a FENCE. Similarly, the lock release is not, by default, constrained from being reordered with respect to the operations before it in the critical section. To avoid this situation, a lock release must be preceded by a FENCE.

TABLE 5.6: Synchronization in TSO vs Synchronization in XC.

Code	TSO	XC
acquire lock	RMW: test-and-set L /* read L, write L=1 if L==1, goto RMW */ if lock held, try again	RMW: test-and-set L /* read L, write L=1 if L==1, goto RMW */ if lock held, try again FENCE
critical section	loads and stores	loads and stores
release lock	store L=0	FENCE store L=0

5.3.2 FENCES with XC

If a core C1 executes some memory operations X_i , then a FENCE, and then memory operations Y_i , the XC implementation must preserve order. Specifically, the XC implementation must order $X_i <_m \text{FENCE} <_m Y_i$. We see three basic approaches:

- An implementation can implement SC and treat all FENCES as no-ops. This is not done (yet) in a commercial product, but there have been academic proposals, e.g., via implicit transactional memory [12].
- An implementation can wait for all memory operations X_i to perform, consider the FENCE done, and then begin memory operations Y_i . This “FENCE as drain” method is common, but it makes FENCES costly.
- An implementation can aggressively push toward what is necessary, enforcing $X_i <_m \text{FENCE} <_m Y_i$, without draining. Exactly how one would do this is beyond the scope of this primer. While this approach may be more complex to design and verify, it can lead to better performance than draining.

In all cases, a FENCE implementation must know when each operation X_i is done (or at least ordered). Knowing when an operation is done can be especially tricky for a store that bypasses the usual cache coherence (e.g., a store to an I/O device or one using some fancy write update optimization).

5.3.3 A Caveat

Finally, an XC implementor might say, “I’m implementing a relaxed model, so anything goes.” This is not true. One must obey the many XC rules, e.g., Load \rightarrow Load order to the same address (this particular ordering is actually non-trivial to enforce in an out-of-order core). Moreover, all XC implementations must be strong enough to provide SC for programs that have FENCES between each pair of instructions because these FENCES require memory order to respect all of the program order.

5.4 SEQUENTIAL CONSISTENCY FOR DATA-RACE-FREE PROGRAMS

Children and computer architects would like “to have their cake and eat it too.” For memory consistency models, this can mean enabling programmers to reason with the (relatively) intuitive model of SC while still achieving the performance benefits of executing on a relaxed model like XC.

Fortunately, simultaneously achieving both goals is possible for the important class of *data-race-free (DRF)* programs [3]. Informally, a data race occurs when two threads access the same memory location, at least one of the accesses is a write, and there are no intervening synchronization

operations. Data races are often, but not always, the result of programming errors and many programmers seek to write DRF programs. *SC for DRF programs* asks programmers to ensure programs are DRF under SC and asks implementors to ensure that all executions of DRF programs on the relaxed model are also SC executions. XC and, as far as we know, all commercial relaxed memory models support SC for DRF programs. Moreover, this approach also serves as a foundation for Java and C++ high-level language (HLL) memory models (Section 5.9).

Let us motivate “SC for DRF” with two examples. Both Table 5.7 and Table 5.8 depict examples in which Core C1 stores two locations (S1 and S2) and Core C2 loads the two locations in the opposite order (L1 and L2). The examples differ because Core C2 does no synchronization in Table 5.7 but acquires the same lock as Core C1 in Table 5.8.

Since Core C2 does no synchronization in Table 5.7, its loads can execute concurrently with Core C1’s stores. Since XC allows Core C1 to reorder stores S1 and S2 (or not) and Core C2 to reorder loads L1 and L2 (or not), four outcomes are possible wherein $(r1, r2) = (0, 0), (0, \text{NEW}), (\text{NEW}, 0),$ or (NEW, NEW) . Output $(0, \text{NEW})$ occurs, for example, if loads and stores execute in the sequence S2, L1, L2, and then S1 or the sequence L2, S1, S2, and then L1. However, this example includes two data races (S1 with L2 and S2 with L1) because Core C2 does not acquire the lock used by Core C1.

Table 5.8 depicts the case in which Core C2 acquires the same lock as acquired by Core C1. In this case, Core C1’s critical section will execute completely before Core C2’s or vice versa. This allows two outcomes: $(r1, r2) = (0, 0)$ or (NEW, NEW) . Importantly, these outcomes are not affected by whether, within their respective critical sections, Core C1 reorders stores S1 and S2 and/or Core C2 reorders loads L1 and L2. “A tree falls in the woods (reordered stores), but no one hears

TABLE 5.7: Example with Four Outcomes for XC with a Data Race.

Core C1	Core C2	Comments
F11: FENCE A11: acquire(lock) F12: FENCE S1: data1 = NEW; S2: data2 = NEW; F13: FENCE R11: release(lock) F14: FENCE	L1: r2 = data2; L2: r1 = data1;	/* Initially, data1 & data2 = 0 */ /* Four Possible Outcomes under XC: (r1, r2) = (0, 0), (0, NEW), (NEW, 0), or (NEW, NEW) But has a Data Race */

TABLE 5.8: Example with Two Outcomes for XC Without a Data Race, Just Like SC.

Core C1	Core C2	Comments
F11: FENCE A11: acquire(lock) F12: FENCE S1: data1 = NEW; S2: data2 = NEW; F13: FENCE R11: release(lock) F14: FENCE	F21: FENCE A21: acquire(lock) F22: FENCE L1: r2 = data2; L2: r1 = data1; F23: FENCE R22: release(lock) F24: FENCE	/* Initially, data1 & data2 = 0 */ /* Two Possible Outcomes under XC: (r1, r2) = (0, 0) or (NEW, NEW) Same as with SC */

it (no concurrent loads).” Moreover, the XC outcomes are the same as would be allowed under SC. “SC for DRF” generalizes from these two examples to claim:

- Either an execution has data races that expose XC’s reordering of loads or stores, or
- the XC execution is data-race-free and indistinguishable from an SC execution.

A more concrete understanding of “SC for DRF” requires some definitions:

- Some memory operations are tagged as *synchronization* (“synchronization operations”), while the rest are tagged *data* by default (“data operations”). Synchronization operations include lock acquires and releases.
- Two data operations D_i and D_j *conflict* if they are from different cores (threads) (i.e., not ordered by program order), access the same memory location, and at least one is a store.
- Two synchronization operations S_i and S_j *conflict* if they are from different cores (threads), access the same memory location (e.g., the same lock), and the two synchronization operations are not compatible (e.g., acquire and release of a spinlock are not compatible, whereas two read_locks on a reader-writer lock are compatible).

- Two synchronization operations S_i and S_j *transitively conflict* if either S_i and S_j conflict or if S_i conflicts with some synchronization operation S_k , $S_k <_p S_{k'}$ (i.e., S_k is earlier than $S_{k'}$ in a core K 's program order), and $S_{k'}$ transitively conflicts with S_j .
- Two data operations D_i and D_j *race* if they conflict and they appear in the global memory order without an intervening pair of transitively conflicting synchronization operations by the same cores (threads) i and j . In other words, a pair of conflicting data operations $D_i <_m D_j$ are *not* a data race if and only if there exists a pair of transitively conflicting synchronization operations S_i and S_j such that $D_i <_m S_i <_m S_j <_m D_j$.
- An SC execution is data-race-free (DRF) if no data operations race.
- A program is DRF if all its SC executions are DRF.
- A memory consistency model supports “SC for DRF programs” if all executions of all DRF programs are SC executions. This support usually requires some special actions for synchronization operations.

Consider the memory model XC. Require that the programmer or low-level software ensures that all synchronization operations are preceded and succeeded by FENCES, as they are in Table 5.8.

With FENCES around synchronization operations, XC supports SC for DRF programs. While a proof is beyond the scope of this work, the intuition behind this result follows from the examples in Table 5.7 and Table 5.8 discussed above.

Supporting SC for DRF programs allows many programmers to reason about their programs with SC and not the more complex rules of XC and, at the same time, benefit from any hardware performance improvements or simplifications XC enables over SC. The catch—and isn't there always a catch?—is that correctly placing FENCES can be challenging:

- It is undecidable to determine *exactly* which memory operations can race and therefore must be tagged as synchronization. Figure 5.4 depicts an execution in which core C2's store should be tagged as synchronization—which determines whether FENCES are actually necessary—only if one can determine whether C1's initial block of code does not halt, which is, of course, undecidable. Undecidability can be avoided by adding FENCES whenever one is unsure whether a FENCE is needed. This is always correct, but may hurt performance. In the limit, one can surround all memory operations by FENCES to ensure SC behavior for *any* program.
- Finally, programs may have data races that violate DRF due to bugs, non-blocking data structures, etc. The bad news is that, after data races, the execution may no longer obey SC, forcing programmers to reason about the underlying relaxed memory model (e.g., XC).

FIGURE 5.4: Optimal Placement of FENCES is Undecidable.

The good news is that all executions will obey SC at least until the first data race, allowing some debugging with SC reasoning only [5].

5.5 SOME RELAXED MODEL CONCEPTS

The academic literature offers many alternative relaxed memory models and concepts. Here we review some relaxed memory concepts from the vast literature to provide a basic understanding, but a full and formal exploration is beyond the scope of this primer. Fortunately, users of SC for DRF, which may be most programmers, do not have to master the concepts in this difficult section. On a first pass, readers may wish to skim or skip this section.

5.5.1 Release Consistency

In the same ISCA 1990 session in which Adve and Hill proposed "SC for DRF," Gharachorloo et al. [14] proposed *release consistency* (RC). Using the terminology of this chapter, the key observation of RC is that surrounding all synchronization operations with FENCES is overkill. With a deeper understanding of synchronization, a synchronization *acquire* needs only a succeeding FENCE, while a synchronization *release* needs only a preceding FENCE.

For the critical section example of Table 5.4, FENCES F11, F14, F21, and F24 may be omitted. Let us focus on "R11: release(lock)." FENCE F13 is important because it orders the critical section's loads (L1i) and stores (S1j) before the lock release. FENCE F14 may be omitted because there is no problem if core C1's subsequent memory operations (none shown in the table) were performed early before release R11.

RC actually allows these subsequent operations to be performed as early as the beginning of the critical section, in contrast to XC's FENCE, which disallows such an ordering. RC provides ACQUIRE and RELEASE operations that are similar to FENCES, but order memory accesses in only one direction instead of in both directions like FENCES. More generally, RC only requires:

ACQUIRE → Load, Store (but not Load, Store → ACQUIRE)
 Load, Store → RELEASE (but not RELEASE → Load, Store)
 and SC ordering of ACQUIREs and RELEASEs:
 ACQUIRE → ACQUIRE
 ACQUIRE → RELEASE
 RELEASE → ACQUIRE, and
 RELEASE → RELEASE

5.5.2 Causality and Write Atomicity

Here we illustrate two subtle properties of relaxed models. The first property, *causality*, requires that, “If I see it and tell you about it, then you will see it too.” For example, consider Table 5.9 where core C1 does a store S1 to update data1. Let core C2 spin until it sees the results of S1 ($r1 == \text{NEW}$), perform FENCE F1, and then do S2 to update data2. Similarly, core C3 spins on load L2 until it sees the result of S2 ($r2 == \text{NEW}$), performs FENCE F2, and then does L3 to observe store S1. If core C3 is guaranteed to observe S1 done ($r3 == \text{NEW}$), then causality holds. On the other hand, if $r3$ is 0, causality is violated.

The second property, *write atomicity* (also called *store atomicity*), requires that a core’s store is logically seen by all other cores at once. XC is write atomic by definition since its memory order ($<m$) specifies a logically atomic point at which a store takes effect at memory. Before this point, no *other* cores may see the newly stored value. After this point, all *other* cores must see the new value or the value from a later store, but not a value that was clobbered by the store. Write atomicity allows a core to see the value of its *own* store before it is seen by other cores, as required by XC, causing some to consider “write atomicity” to be a poor name.

TABLE 5.9: Causality: If I See a Store and Tell You About It, Must You See It Too?

Core C1	Core C2	Core C3
S1: data1 = NEW;	L1: r1 = data1; B1: if (r1 ≠ NEW) goto L1; F1: FENCE S2: data2 = NEW;	/* Initially, data1 & data2 = 0 */ L2: r2 = data2; B2: if (r2 ≠ NEW) goto L2; F2: FENCE L3: r3 = data1; /* r3 == NEW? */

TABLE 5.10: IRIW Example: Must Stores Be in Some Order?

Core C1	Core C2	Core C3	Core C4
S1: data1 = NEW;	S2: data2 = NEW;	L1: r1 = data1; /* NEW */ F1: FENCE L2: r2 = data2; /* NEW? */	/* Initially, data1 & data2 = 0 */ L3: r3 = data2; /* NEW */ F2: FENCE L4: r4 = data1; /* NEW? */

A necessary, but not sufficient, condition for write atomicity is proper handling of the *Independent Read Independent Write (IRIW)* example. IRIW is depicted in Table 5.10 where cores C1 and C2 do stores S1 and S2, respectively. Assume that core C3's load L1 observes S1 ($r1 == \text{NEW}$) and core C4's L3 observes S2 ($r3 == \text{NEW}$). What if C3's L2 loads 0 ($r2 == 0$) and C4's L4 loads 0 ($r4 == 0$)? The former implies that core C3 sees store S1 before it sees S2, while the latter implies that C4 sees S2 before S1. In this case, stores S1 and S2 are not just "reordered," but *no order of stores even exists*, and write atomicity is violated. The converse is not necessarily true: proper handling of IRIW does not automatically imply store atomicity. Some more facts (that can make your head hurt and long for SC, TSO, or SC for DRF):

- Write atomicity implies causality. In Table 5.9, for example, core C2 observes store S1, performs a FENCE, and then does store S2. With write atomicity, this ensures C3 sees store S1 as done.
- Causality does *not* imply write atomicity. For Table 5.10, assume that cores C1 and C3 are two thread contexts of a multithreaded core that share a write buffer. Assume the same for cores C2 and C4. Let C1 put S1 in the C1–C3 write buffer, so it is observed by C3's L1 only. Similarly, C2 puts S2 into the C2–C4 write buffer, so S2 is observed by C4's L3 only. Let both C3 do L2 and C4 do L4 before either store leaves the write buffers. This execution violates write atomicity. Using the example in Table 5.9, however, one can see that this design provides causality.

Finally, the XC memory model is both store atomic and maintains causality. We previously argued that XC was store atomic. XC maintains causality because store atomicity implies causality.

5.6 A RELAXED MEMORY MODEL CASE STUDY: IBM POWER

IBM Power implements the Power memory model [17] (see especially Book II's Chapter 1, Section 4.4, and Appendix B). We attempt to give the gist of the Power memory model here, but we refer the reader to the Power manual for the definitive presentation, especially for programming

Power. We do not provide an ordering table like Table 5.5 for SC because we are not confident we could specify all entries correctly. We discuss normal cacheable memory only (“Memory Coherence” enabled, “Write Through Required” disabled, and “Caching Inhibited” disabled) and not I/O space, etc. PowerPC [18] represents earlier versions of the current Power model. On a first pass of this primer, readers may wish to skim or skip this section; this memory model is significantly more complicated than the models presented thus far in this primer.

Power provides a relaxed model that is superficially similar to XC but with important differences that include the following.

First, stores in Power are performed *with respect to (w.r.t.) other cores*, not w.r.t. memory. A store by core C1 is “performed w.r.t.” core C2 when any loads by core C2 to the same address will see the newly stored value or a value from a later store, but not the previous value that was clobbered by the store. Power ensures that if core C1 uses FENCES to order store S1 before S2 and before S3, then the three stores will be performed w.r.t. every other core C_i in the same order. In the absence of FENCES, however, core C1’s store S1 may be performed w.r.t. core C2 but not yet performed w.r.t. to C3. Thus, Power is not guaranteed to create a total memory order ($<m$) as did XC.

Second, some FENCES in Power are defined to be *cumulative*. Let a core C2 execute some memory accesses X_1, X_2, \dots , a FENCE, and then some memory accesses Y_1, Y_2, \dots . Let set $X = \{X_i\}$ and set $Y = \{Y_i\}$. (The Power manual calls these sets A and B, respectively.) Define *cumulative* to mean three things: (a) add to set X the memory accesses by *other* cores that are ordered before the FENCE (e.g., add core C1’s store S1 to X if S1 is performed w.r.t. core C2 before C2’s FENCE); (b) add to set Y the memory accesses by *other* cores that are ordered after the FENCE by data dependence, control dependence, or another FENCE; and (c) apply (a) recursively backward (e.g., for cores that have accesses previously ordered with core C1) and apply (b) recursively forward. (FENCES in XC are also cumulative, but their cumulative behavior is automatically provided by XC’s total memory order, not by the FENCES specifically.)

Third, Power has three kinds of FENCES (and more for I/O memory), whereas XC has only one FENCE.

- SYNC or HWSYNC (“HW” means “heavy weight” and “SYNC” stands for “synchronization”) orders all accesses X before all accesses Y and is cumulative.
- LWSYNC (“LW” means “light weight”) orders loads in X before loads in Y, orders loads in X before stores in Y, and orders stores in X before stores in Y. LWSYNC is cumulative. Note that LWSYNC does *not* order stores in X before loads in Y.
- ISYNC (“I” means “instruction”) is sometimes used to order two loads from the same core, but it is not cumulative and, despite its name, it is not a FENCE like HWSYNC and LWSYNC, because it orders instructions and not memory accesses. For these reasons, we do not use ISYNC in our examples.

Fourth, Power orders accesses in some cases even without FENCES. For example, if load L1 obtains a value used to calculate an effective address of a subsequent load L2, then Power orders load L1 before load L2. Also, if load L1 obtains a value used to calculate an effective address or data value of a subsequent store S2, then Power orders load L1 before store S2.

Table 5.11 illustrates Power's LWSYNC in action. Core C1 executes a LWSYNC to order data stores S1 and S2 before S3. Note that the LWSYNC does not order stores S1 and S2 with respect to each other, but this is not needed. A LWSYNC provides sufficient order here because it orders stores in X (S1 and S2) before stores in Y (S3). Similarly, core C2 executes a LWSYNC after its conditional branch B1 to ensure that load L1 completes with r1 assigned to SET before loads L2 and L3 execute. HWSYNC is not required because neither core needs to order stores before loads.

Table 5.12 illustrates Power's HWSYNC in action on a key part of Dekker's algorithm. The HWSYNCS ensure core C1's store S1 is before load L1 and core C2's store S2 is before load S2. This prevents the execution from terminating with r1=0 and r2=0. Using LWSYNC would not prevent this execution because an LWSYNC does not order earlier stores before later loads.

As depicted in Table 5.13, Power's LWSYNCS can be used to make the causality example from Table 5.9 behave sensibly (i.e., r3 is always set to NEW). LWSYNC F1 is executed only after load L1 sees the new value of data1, which means that store S1 has been performed w.r.t. core C2. LWSYNC F1 orders S1 before S2 with respect to core C2 by the cumulative property. LWSYNC F2 is executed only after load L2 sees the new value of data2, which means that store S2 has been performed w.r.t. core C3. The cumulative property also ensures that store S1 has been performed

TABLE 5.11: Power LWSYNCS to Ensure r2 & r3 Always Get NEW.

Core C1	Core C2	Comments
S1: data1 = NEW; S2: data2 = NEW; F1: LWSYNC S3: flag = SET;	L1: r1 = flag; B1: if (r1 ≠ SET) goto L1; F2: LWSYNC L2: r2 = data1; L3: r3 = data2;	/* Initially, data1 & data2 = 0 & flag ≠ SET */ /* Ensures S1 and S2 before S3 */ /* spin loop: L1 & B1 may repeat many times */ /* Ensure B1 before L2 and L3 */

TABLE 5.12: Power HWSYNCS to Ensure Both r1 and r2 are Not Set to 0.

Core C1	Core C2	Comments
S1: x = NEW; F1: HWSYNC L1: r1 = y;	S2: y = NEW; F2: HWSYNC L2: r2 = x;	/* Initially, x = 0 & y = 0 */ /* Ensures Si before Li for i = 1,2 */

w.r.t. core C3 before S2 (because of LWSYNC F1). Finally, LWSYNC F2 orders load L2 before L3, ensuring r3 obtains the value NEW.

As depicted in Table 5.14, Power's HWSYNCS can be used to make the Independent Read Independent Write Example (IRIW) of Table 5.10 behave sensibly (i.e., disallowing the result r1==NEW, r2==0, r3==NEW and r4==0). Using LWSYNCS is not sufficient. For example, core C3's F1 HWSYNC must cumulatively order core C1's store S1 before core C3's load L2. In any case, this does not show that Power has write atomicity as defined in Section 5.5.2.

An alternative way to look at the Power memory model is to specify the FENCES needed to make Power behave like stronger memory models. To this end:

- Power can be restricted to SC executions by inserting an HWSYNC between each pair of memory-accessing instructions.
- Power can be restricted to TSO executions by inserting an LWSYNC between each pair of memory-accessing instructions and replacing each FENCE with an HWSYNC.

TABLE 5.13: Power LWSYNCS to Ensure Causality (r3 == NEW).

Core C1	Core C2	Core C3
S1: data1 = NEW;	L1: r1 = data1; B1: if (r1 ≠ NEW) goto L1; F1: LWSYNC S2: data2 = NEW;	/* Initially, data1 & data2 = 0 */ L2: r2 = data2; B2: if (r2 ≠ NEW) goto L2; F2: LWSYNC L3: r3 = data1; /* r3 == NEW? */

TABLE 5.14: Power LWSYNCS with the IRIW Example.

Core C1	Core C2	Core C3	Core C4
S1: data1 = NEW;	S2: data2 = NEW;	L1: r1 = data1; /* NEW */ F1: HWSYNC L2: r2 = data2; /* NEW? */	/* Initially, data1 & data2 = 0 */ L3: r3 = data2; /* NEW */ F2: HWSYNC L4: r4 = data1; /* NEW? */

The above is a thought experiment, and it is definitely not a recommended way to achieve good performance on Power.

5.7 FURTHER READING AND COMMERCIAL RELAXED MEMORY MODELS

5.7.1 Academic Literature

Below are a few highlights from the vast relaxed memory consistency literature. Among the first developed relaxed models was that of Dubois et al. [13] with *weak ordering*. Adve and Hill generalized weak ordering to the order strictly necessary for programmers with “SC for DRF” [3, 4]. Gharachorloo et al. [14] developed release consistency, as well as “proper labeling” (that can be viewed as a generalization of “SC for DRF”) and a model that allows synchronization operations to follow TSO (“RC_{PC}”). Adve and Gharachorloo [2] wrote a seminal memory model tutorial summarizing the state of the art in the mid-1990s.

As far as we know, Meixner and Sorin [23, 24] were the first to prove correctness of a relaxed memory model realized by separating the cores and the cache-coherent memory system with a re-order unit governed by certain rules.

It is notoriously difficult to specify and verify both strong and relaxed memory models. To this end, Alglave et al. [6, 7] have developed formal specifications and, importantly, the downloadable *diy* tool [1] that generates discerning litmus tests to randomly run on x86 and Power. As with all testing, *diy* can find bugs, but not prove hardware correct.

5.7.2 Commercial Models

In addition to Power [17], commercial relaxed memory models include Alpha [26], SPARC RMO [27], and ARM [9, 8].

Alpha [26] is largely defunct, but, like XC, assumes a total memory order. Alpha retains some importance because it had a large influence on Linux synchronization since Linux ran on Alpha [22] (see especially Chapter 12 and Appendix C). McKenney [22] points out that Alpha did

not order two loads even if the first provided the effective address for the second. More generally, McKenney's online book is a good source of information on Linux synchronization and its interaction with memory consistency models.

SPARC Relaxed Memory Order (RMO) [27] also provides a total memory order like XC. Although SPARC allows the operating system to select a memory model among TSO, PSO, and RMO, all current SPARC implementations operate with TSO in all cases. TSO is a valid implementation of PSO and RMO since it is strictly stronger.

ARM [9, 8] provides a memory model similar in spirit to IBM Power. Like Power, it appears to not guarantee a total memory order. Like Power, ARM has multiple flavors of FENCEs, including a data memory barrier that can order all memory access or just stores and an instruction synchronization barrier like Power's ISYNC, as well as other FENCEs for I/O operations.

5.8 COMPARING MEMORY MODELS

5.8.1 How Do Relaxed Memory Models Relate to Each Other and TSO and SC?

Recall that a memory consistency model Y is strictly more *relaxed* (*weaker*) than a memory consistency model X if all X executions (implementations) are also Y executions (implementations), but not vice versa. It is also possible that two memory consistency models are incomparable because both allow executions (implementations) precluded by the other.

Figure 5.5 repeats a figure from the previous chapter where Power replaces the previously unspecified MC1, while MC2 could be Alpha, ARM, RMO, or XC. How do they compare?

- Power is more relaxed than TSO which is more relaxed than SC.
- Alpha, ARM, RMO, and XC are more relaxed than TSO which is more relaxed than SC.
- Power is assumed to be incomparable with respect to Alpha, ARM, RMO, and XC until someone proves that one is more relaxed than the other or that the two are equivalent.

FIGURE 5.5: Comparing Memory Consistency Models.

Mador-Haim et al. [20] have developed an automated technique for comparing memory consistency models—including SC, TSO, and RMO—but they did not consider ARM or Power. ARM and Power may be equivalent, but we await a proof.

5.8.2 How Good Are Relaxed Models?

As discussed in the previous chapter, a good memory consistency model should possess Sarita Adve’s 3Ps plus our fourth P:

- *Programmability*: Relaxed model programmability is acceptable for those who use “SC for DRF.” Deeply understanding a relaxed model (e.g., to write compilers and runtime systems) is difficult.
- *Performance*: Relaxed memory models can offer better performance than TSO, but the difference is smaller for many core micro-architectures.
- *Portability*: Porting while staying within “SC for DRF” is manageable. Pushing the limits of relaxed models, especially those that are incomparable, is hard.
- *Precise*: Many relaxed models are only informally defined. Moreover, formal definitions of relaxed models tend to be obtuse.

The bottom line is that ... there is no simple bottom line.

5.9 HIGH-LEVEL LANGUAGE MODELS

The previous two chapters and this chapter so far address memory consistency models at the interface between hardware and low-level software, discussing (a) what software authors should expect and (b) what hardware implementors may do.

It is also important to define memory models for high-level languages (HLLs), specifying (a) what HLL software authors should expect and (b) what implementors of compilers, runtime

FIGURE 5.6: (a) High-Level Language (HLL) and (b) Hardware Memory Models.

systems, and hardware may do. Figure 5.6 illustrates the difference between (a) high-level and (b) low-level memory models.

Because many HLLs emerged in a largely single-threaded world, their specifications omitted a memory model. (Do you remember one in Kernighan and Ritchie [19]?) Java was perhaps the first mainstream language to have a memory model, but the first version had some issues [25].

Recently, however, memory models have been re-specified for Java [21] and specified for C++ [10]. Fortunately, the cornerstone of both models is a familiar one—SC for DRF [3]—provided in part by Sarita Adve’s coauthorship of all three papers. To allow synchronization races but not data races, programmers must tag variables as synchronization when it is possible they can race, using keywords such as **volatile** and **atomic**, or create synchronization locks implicitly with Java’s monitor-like **synchronized** methods. In all cases, implementations are free to reorder references as long as data-race-free programs obey SC.

In particular, implementations can reorder or eliminate memory accesses between synchronization accesses. Table 5.15 illustrates an example. Table 5.15(a) presents the HLL code, and Table 5.15(b) and (c) show executions on core C1 both without register allocation and with variable A allocated in register r1 so that load L3 is reordered and merged with load L1. This reordering is correct because, with “SC for DRF,” no other thread “can be looking.” In addition to register allocation, many, if not most, compiler and runtime optimizations—such as constant propagation, common subexpression elimination, loop fission/fusion, loop invariant code motion, software pipelining, and instruction scheduling—can reorder memory accesses. Because “SC for DRF” allows these optimizations, compilers and runtime systems can produce code with performance that is comparable to single-threaded code.

What if an HLL program has data races by accident or on purpose? In this case, another thread could observe a non-SC execution. For Table 5.15, core C2 (not shown) could update A and C and have core C1 observe the update to C but not A, which has been register allocated. This execution violates SC at the HLL level.

More generally, what are the limits on what threads can observe with data races? Java, in particular, requires security guarantees for all programs. For this reason, Java specifies behavior in all cases with the following goals:

1. allow almost all optimizations for high-performance DRF programs,
2. unambiguously, specify the allowed behavior of all programs, and
3. make this unambiguous specification simple.

In our judgment, the 2005 Java memory model made substantial progress, arguably succeeding on (1) and (2), but not (3). Fortunately, most programmers can use “SC for DRF” and not

TABLE 5.15: Register Allocation Affects Memory Order.

program order (<p)

memory order (<m)

suffer the consequences of the “dark corners” of the Java memory model. Authors of compilers and runtime software, however, must confront them at some level. Consider this “dark corner” that must be understood: regardless of optimizations, a load to address *A* must always return a value stored to address *A* at some time (perhaps at initialization) and not a value “out of thin air.” Unfortunately, this is not the only example of complexity that must be confronted.

Flashback to Quiz Question 5: A programmer who writes properly synchronized code relative to the high-level language consistency model (e.g., Java) does not need to consider the architecture’s memory consistency model. *True or false?*

Answer: It depends. For typical application programmers, the answer is *True*, because their programs behave as expected (SC is expected). For the programmers of compilers and runtime systems, the answer is *False*.

Thus, HLLs, such as Java and C++, adopt the relaxed memory model approach of “SC for DRF.” When these HLLs run on hardware, should the hardware’s memory model also be relaxed? On one hand, (a) relaxed hardware can give the most performance, and (b) compilers and runtime software need only translate the HLL’s synchronizations operations into the particular hardware’s low-level synchronization operations and FENCES to provide the necessary ordering. On the other hand, (a) SC and TSO can give good performance, and (b) compilers and runtime software can generate more portable code without FENCES from incomparable memory models. Although the debate is not settled, it is clear that relaxed HLL models do not *require* relaxed hardware.

CHAPTER 6

Coherence Protocols

In this chapter, we return to the topic of cache coherence that we introduced in Chapter 2. We defined coherence in Chapter 2, in order to understand coherence’s role in supporting consistency, but we did not delve into how specific coherence protocols work or how they are implemented. This chapter discusses coherence protocols in general, before we move on to specific classes of protocols in the next two chapters. We start in Section 6.1 by presenting the big picture of how coherence protocols work, and then show how to specify protocols in Section 6.2. We present one simple, concrete example of a coherence protocol in Section 6.3 and explore the protocol design space in Section 6.4.

6.1 THE BIG PICTURE

The goal of a coherence protocol is to maintain coherence by enforcing the invariants introduced in Section 2.3 and restated here:

1. *Single-Writer, Multiple-Read (SWMR) Invariant.* For any memory location A , at any given (logical) time, there exists only a single core that may write to A (and can also read it) or some number of cores that may only read A .
2. *Data-Value Invariant.* The value of the memory location at the start of an epoch is the same as the value of the memory location at the end of its last read-write epoch.

To implement these invariants, we associate with each storage structure—each cache and the LLC/memory—a finite state machine called a *coherence controller*. The collection of these coherence controllers constitutes a distributed system in which the controllers exchange messages with each other to ensure that, for each block, the SWMR and data value invariants are maintained at all times. The interactions between these finite state machines are specified by the coherence protocol.

Coherence controllers have several responsibilities. The coherence controller at a cache, which we refer to as a *cache controller*, is illustrated in Figure 6.1. The cache controller must service requests from two sources. On the “core side,” the cache controller interfaces to the processor core.

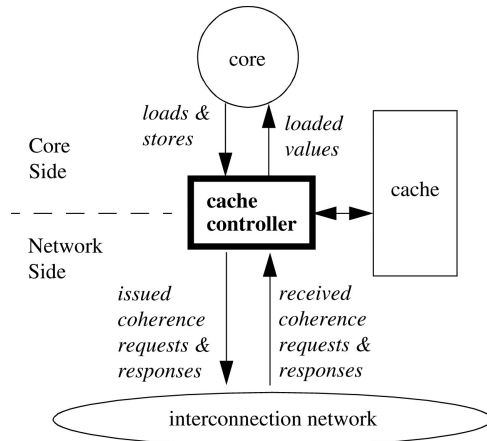

FIGURE 6.1: Cache controller.

FIGURE 6.2: Memory controller.

The controller accepts loads and stores from the core and returns load values to the core. A cache miss causes the controller to initiate a coherence *transaction* by issuing a coherence *request* (e.g., request for read-only permission) for the block containing the location accessed by the core. This coherence request is sent across the interconnection network to one or more coherence controllers. A transaction consists of a request and the other message(s) that are exchanged in order to satisfy the request (e.g., a data response message sent from another coherence controller to the requestor). The types of transactions and the messages that are sent as part of each transaction depend on the specific coherence protocol.

On the cache controller’s “network side,” the cache controller interfaces to the rest of the system via the interconnection network. The controller receives coherence requests and coherence responses that it must process. As with the core side, the processing of incoming coherence messages depends on the specific coherence protocol.

The coherence controller at the LLC/memory, which we refer to as a *memory controller*, is illustrated in Figure 6.2. A memory controller is similar to a cache controller, except that it usually has only a network side. As such, it does not issue coherence requests (on behalf of loads or stores) or receive coherence responses. Other agents, such as I/O devices, may behave like cache controllers, memory controllers, or both depending upon their specific requirements.

Each coherence controller implements a set of finite state machines—logically one independent, but identical finite state machine per block—and receives and processes *events* (e.g., incoming coherence messages) depending upon the block’s state. For an event of type E (e.g., a store request

from the core to the cache controller) to block B, the coherence controller takes actions (e.g., issues a coherence request for read-write permission) that are a function of E and of B's *state* (e.g., read-only). After taking these actions, the controller may change the state of B.

6.2 SPECIFYING COHERENCE PROTOCOLS

We specify a coherence protocol by specifying the coherence controllers. We could specify coherence controllers in any number of ways, but the particular behavior of a coherence controller lends itself to a tabular specification [9]. As shown in Table 6.1, we can specify a controller as a table in which rows correspond to block states and columns correspond to events. We refer to a state/event entry in the table as a *transition*, and a transition for event E pertaining to block B consists of (a) the actions taken when E occurs and (b) the next state of block B. We express transitions in the format “action/next state” and we may omit the “next state” portion if the next state is the current state. As an example of a transition in Table 6.1, if a store request for block B is received from the core and block B is in a read-only state (RO), then the table shows that the controller's transition will be to perform the action “issue coherence request for read-write permission [to block B]” and change the state of block B to RW.

The example in Table 6.1 is intentionally incomplete, for simplicity, but it illustrates the capability of a tabular specification methodology to capture the behavior of a coherence controller. To specify a coherence protocol, we simply need to completely specify the tables for the cache controllers and the memory controllers.

TABLE 6.1: Tabular Specification Methodology. This is an Incomplete Specification of a Cache Coherence Controller. Each Entry in the Table Specifies the Actions Taken and the Next State of the Block.

		Events		
		load request from core	store request from core	incoming coherence request to obtain block in read-write state
States	not readable or writeable (N)	issue coherence request for read-only permission/RO	issue coherence request for read-write permission/RW	<no action>
	read-only (RO)	give data from cache to core	issue coherence request for read-write permission/RW	<no action>/N
	read-write (RW)	give data from cache to core/RO	write data to cache	send block to requestor/N

The differences between coherence protocols lie in the differences in the controller specifications. These differences include different sets of block states, transactions, events, and transitions. In Section 6.4, we describe the coherence protocol design space by exploring the options for each of these aspects, but we first specify one simple, concrete protocol.

6.3 EXAMPLE OF A SIMPLE COHERENCE PROTOCOL

To help understand coherence protocols, we now present a simple protocol. Our system model is the baseline system model from Section 2.1, but with the interconnection network restricted to being a shared bus: a shared set of wires on which a core can issue a message and have it observed by all cores and the LLC/memory.

Each cache block can be in one of two stable coherence states: I(nvalid) and V(alid). Each block at the LLC/memory can also be in one of two coherence states: I and V. At the LLC/memory, the state I denotes that all caches hold the block in state I, and the state V denotes that one cache holds the block in state V. There is also a single transient state for cache blocks, IV^D , discussed below. At system startup, all cache blocks and LLC/memory blocks are in state I. Each core can issue load and store requests to its cache controller; the cache controller will implicitly generate an Evict Block event when it needs to make room for another block. Loads and stores that miss in the cache initiate coherence transactions, as described below, to obtain a valid copy of the cache block. Like all the protocols in this primer, we assume a writeback cache; that is, when a store hits, it writes the store value only to the (local) cache and waits to write the entire block back to the LLC/memory in response to an Evict Block event.

There are two types of coherence transactions implemented using three types of bus messages: *Get* requests a block, *DataResp* transfers the block's data, and *Put* writes the block back to the memory controller. On a load or store miss, the cache controller initiates a Get transaction by sending a Get message and waiting for the corresponding DataResp message. The Get transaction is atomic in that no other transaction (either Get or Put) may use the bus between when the cache sends the Get and when the DataResp for that Get appears on the bus. On an Evict Block event, the cache controller sends a Put message, with the entire cache block, to the memory controller.

We illustrate the transitions between the stable coherence states in Figure 6.3. We use the prefaces “Own” and “Other” to distinguish messages for transactions initiated by the given cache controller versus those initiated by other cache controllers. Note that if the given cache controller has the block in state V and another cache requests it with a Get message (denoted Other-Get), the owning cache must respond with a block (using a DataResp message, not shown) and transition to state I.

Table 6.2 and Table 6.3 specify the protocol in more detail. Shaded entries in the table denote impossible transitions. For example, a cache controller should never see its own Put request on the bus for a block that is in state V in its cache (as it should have already transitioned to state I).

FIGURE 6.3: Transitions between stable states of blocks at cache controller.

The transient state IV^D corresponds to a block in state I that is waiting for data (via a DataResp message) before transitioning to state V. Transient states arise when transitions between stable states are not atomic. In this simple protocol, individual message sends and receives are atomic, but fetching a block from the memory controller requires sending a Get message and receiving a DataResp message, with an indeterminate gap in between. The IV^D state indicates that the protocol is waiting for a DataResp. We discuss transient states in more depth in Section 6.4.1.

This coherence protocol is simplistic and inefficient in many ways, but the goal in presenting this protocol is to gain an understanding of how protocols are specified. We use this specification methodology throughout this book when presenting different types of coherence protocols.

TABLE 6.2: Cache Controller Specification. Shaded Entries are Impossible and Blank Entries Denote Events That are Ignored.

States	Core Events		Bus Events					
			Messages for Own Transactions			Messages for Other Cores' Transactions		
	Load or Store	Evict Block	Own-Get	DataResp for Own-Get	Own-Put	Other-Get	DataResp for Other-Get	Other-Put
I	issue Get / IV^D							
IV^D	stall Load or Store	stall Evict		copy data into cache, perform Load or Store /V				
V	perform Load or Store	Issue Put (with data) /I				Send DataResp /I		

TABLE 6.3: Memory Controller Specification		
State	Bus Events	
	Get	Put
I	send data block in DataResp message to requestor/V	
V		Update data block in memory/I

6.4 OVERVIEW OF COHERENCE PROTOCOL DESIGN SPACE

As mentioned in Section 6.1, a designer of a coherence protocol must choose the states, transactions, events, and transitions for each type of coherence controller in the system. The choice of stable states is largely independent of the rest of the coherence protocol. For example, there are two different classes of coherence protocols called snooping and directory, and an architect can design a snooping protocol or a directory protocol with the same set of stable states. We discuss stable states, independent of protocols, in Section 6.4.1. Similarly, the choice of transactions is also largely independent of the specific protocol, and we discuss transactions in Section 6.4.2. However, unlike the choices of stable states and transactions, the events, transitions and specific transient states are highly dependent on the coherence protocol and cannot be discussed in isolation. Thus, in Section 6.4.3, we discuss a few of the major design decisions in coherence protocols.

6.4.1 States

In a system with only one actor (e.g., a single core processor without coherent DMA), the state of a cache block is either valid or invalid. There might be two possible valid states for a cache block if there is a need to distinguish blocks that are *dirty*. A dirty block has a value that has been written more recently than other copies of this block. For example, in a two-level cache hierarchy with a write-back L1 cache, the block in the L1 may be dirty with respect to the stale copy in the L2 cache.

A system with multiple actors can also use just these two or three states, as in Section 6.3, but we often want to distinguish between different kinds of valid states. There are four characteristics of a cache block that we wish to encode in its state: validity, dirtiness, exclusivity, and ownership [10]. The latter two characteristics are unique to systems with multiple actors.

- **Validity:** A *valid* block has the most up-to-date value for this block. The block may be read, but it may only be written if it is also exclusive.

- **Dirtiness:** As in a single core processor, a cache block is *dirty* if its value is the most up-to-date value, this value differs from the value in the LLC/memory, and the cache controller is responsible for eventually updating the LLC/memory with this new value. The term *clean* is often used as the opposite of dirty.
- **Exclusivity:** A cache block is *exclusive*¹ if it is the only privately cached copy of that block in the system (i.e., the block is not cached anywhere else except perhaps in the shared LLC).
- **Ownership:** A cache controller (or memory controller) is the *owner* of a block if it is responsible for responding to coherence requests for that block. In most protocols, there is exactly one owner of a given block at all times. A block that is owned may not be evicted from a cache to make room for another block—due to a capacity or conflict miss—without giving the ownership of the block to another coherence controller. Non-owned blocks may be evicted silently (i.e., without sending any messages) in some protocols.

In this section, we first discuss some commonly used *stable states*—states of blocks that are not currently in the midst of a coherence transaction—and then discuss the use of *transient states* for describing blocks that are currently in the midst of transactions.

6.4.1.1 Stable States

Many coherence protocols use a subset of the classic five state MOESI model first introduced by Sweazey and Smith [10]. These MOESI (often pronounced either “MO-sey” or “mo-EE-see”) states refer to the states of blocks in a cache, and the most fundamental three states are MSI; the O and E states may be used, but they are not as basic. Each of these states has a different combination of the characteristics described above.

- **M(odified):** The block is valid, exclusive, owned, and potentially dirty. The block may be read or written. The cache has the only valid copy of the block, the cache must respond to requests for the block, and the copy of the block at the LLC/memory is potentially stale.
- **S(hared):** The block is valid but not exclusive, not dirty, and not owned. The cache has a read-only copy of the block. Other caches may have valid, read-only copies of the block.
- **I(nvalid):** The block is invalid. The cache either does not contain the block or it contains a potentially stale copy that it may not read or write. In this primer, we do not distinguish between these two situations, although sometimes the former situation may be denoted as the “Not Present” state.

¹The terminology here can be confusing, because there is a cache coherence state that is called “Exclusive,” but there are other cache coherence states that are exclusive in the sense defined here.

The most basic protocols use only the MSI states, but there are reasons to add the O and E states to optimize certain situations. We will discuss these optimizations in later chapters when we discuss snooping and directory protocols with and without these states. For now, here is the complete list of MOESI states:

- M(odified)
- O(wned): The block is valid, owned, and potentially dirty, but not exclusive. The cache has a read-only copy of the block and must respond to requests for the block. Other caches may have a read-only copy of the block, but they are not owners. The copy of the block in the LLC/memory is potentially stale.
- E(xclusive): The block is valid, exclusive, and clean. The cache has a read-only copy of the block. No other caches have a valid copy of the block, and the copy of the block in the LLC/memory is up-to-date. In this primer, we consider the block to be owned when it is in the Exclusive state, although there are protocols in which the Exclusive state is not treated as an ownership state. When we present MESI snooping and directory protocols in later chapters, we discuss the issues involved with making Exclusive blocks owners or not.
- S(hared)
- I(nvalid)

We illustrate a Venn diagram of the MOESI states in Figure 6.4. The Venn diagram shows which states share which characteristics. All states besides I are valid. M, O, and E are ownership states. Both M and E denote exclusivity, in that no other caches have a valid copy of the block. Both

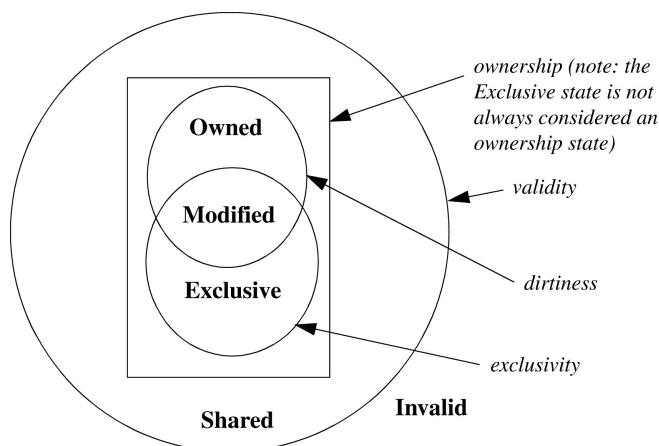

FIGURE 6.4: MOESI states.

M and O indicate that the block is potentially dirty. Returning to the simplistic example in Section 6.3, we observe that the protocol effectively condensed the MOES states into the V state.

The MOESI states, although quite common, are not an exhaustive set of stable states. For example, the F(orward) state is similar to the O state except that it is clean (i.e., the copy in the LLC/memory is up-to-date). There are many possible coherence states, but we focus our attention in this primer on the well-known MOESI states.

6.4.1.2 Transient States

Thus far we have discussed only the stable states that occur when there is no current coherence activity for the block, and it is only these stable states that are used when referring to a protocol (e.g., “a system with a MESI protocol”). However, as we saw even in the example in Section 6.3, there may exist transient states that occur during the transition from one stable state to another stable state. In Section 6.3, we had the transient state IV^D (in I, going to V, waiting for DataResp). In more sophisticated protocols, we are likely to encounter dozens of transient states. We encode these states using a notation XY^Z , which denotes that the block is transitioning from stable state X to stable state Y, and the transition will not complete until an event of type Z occurs. For example, in a protocol in a later chapter, we use IM^D to denote that a block was previously in I and will become M once a D(ata) message arrives for that block.

6.4.1.3 States of Blocks in the LLC/Memory

The states that we have discussed thus far—both stable and transient—pertain to blocks residing in caches. Blocks in the LLC and memory also have states associated with them, and there are two general approaches to naming states of blocks in the LLC and memory. The choice of naming convention does not affect functionality or performance; it is simply a specification issue that can confuse an architect unfamiliar with the convention.

- **Cache-centric:** In this approach, which we believe to be the most common, the state of a block in the LLC and memory is an aggregation of the states of this block in the caches. For example, if a block is in all caches in I, then the LLC/memory state for this block is I. If a block is in one or more caches in S, then the LLC/memory state is S. If a block is in a single cache in M, then the LLC/memory state is M.
- **Memory-centric:** In this approach, the state of a block in the LLC/memory corresponds to the *memory controller's* permissions to this block (rather than the permissions of the caches). For example, if a block is in all caches in I, then the LLC/memory state for this block is O (not I, as in the cache-centric approach), because the LLC/memory behaves like an owner

of the block. If a block is in one or more caches in S, then the LLC/memory state is also O, for the same reason. However, if the block is in a single cache in M or O, then the LLC/memory state is I, because the LLC/memory has an invalid copy of the block.

All protocols in this primer use *cache-centric* names for the states of blocks in the LLC and memory.

6.4.1.4 Maintaining Block State

The system implementation must maintain the states associated with blocks in caches, the LLC, and memory. For caches and the LLC, this generally requires extending the per-block cache state by at most a few bits, since the number of stable states is generally small (e.g., 5 states for a MOESI protocol requires 3 bits per block). Coherence protocols may have many more transient states, but need maintain these states only for those blocks that have pending coherence transactions. Implementations typically maintain these transient states by adding additional bits to the miss status handling registers (MSHRs) or similar structures that are used to track these pending transactions [4].

For memory, it might appear that the much greater aggregate capacity would pose a significant challenge. However, many current multicore systems maintain an inclusive LLC, which means that the LLC maintains a copy of every block that is cached anywhere in the system (even “exclusive” blocks). With an inclusive LLC, memory does not need to explicitly represent the coherence state. If a block resides in the LLC, its state in memory is the same as its state in the LLC. If the block is not in the LLC, its state in memory is implicitly Invalid, because absence from an inclusive LLC implies that the block is not in any cache. The sidebar discusses how memory state was maintained in the days before multicores with inclusive LLCs. The above discussion of memory assumes a system with a single multicore chip, as does most of this primer. Systems with multiple multicore chips may benefit from explicit coherence state logically at memory.

6.4.2 Transactions

Most protocols have a similar set of transactions, because the basic goals of the coherence controllers are similar. For example, virtually all protocols have a transaction for obtaining Shared (read-only) access to a block. In Table 6.4 we list a set of common transactions and, for each transaction, we describe the goal of the requestor that initiates the transaction. These transactions are all initiated by cache controllers that are responding to requests from their associated cores. In Table 6.5, we list the requests that a core can make to its cache controller and how these core requests can lead the cache controller into initiating coherence transactions.

Sidebar: Before Multicores: Maintaining Coherence State at Memory

Traditional, pre-multicore snooping protocols needed to maintain coherence state for each block of memory, and they could not use the LLC as explained in Section 6.4.1.4. We briefly discuss several ways of maintaining this state and the associated engineering tradeoffs.

Augment Each Block of Memory with State Bits. The most general implementation is to add extra bits to each block of memory to maintain the coherence state. If there are N possible states at memory, then each block needs $\log_2 N$ extra bits. Although, this design is fully general and conceptually straightforward, it has several drawbacks. First, the extra bits may increase cost in two ways. Adding two or three extra bits is difficult with modern block-oriented DRAM chips, which are typically at least 4-bits wide and frequently much wider. Plus any change in the memory precludes using commodity DRAM modules (e.g., DIMMs), which significantly increases cost. Fortunately, for protocols that require only a few bits of state per block it is possible to store these using a modified ECC code. By maintaining ECC on a larger granularity (e.g., 512 bits rather than 64 bits), it is possible to free up enough code space to “hide” a handful of extra bits while using commodity DRAM modules [5, 7, 1]. The second drawback is that storing the state bits in DRAM means that obtaining the state incurs the full DRAM latency, even in the case that the most recent version of the block is stored in some other cache. In some cases, this may increase the latency of cache-to-cache coherence transfers. Finally, storing the state in DRAM means that all state changes require a DRAM read-modify-write cycle, which may impact both power and DRAM bandwidth.

Add Single State Bit per Block at Memory. A design option used by the Synapse [3] was to distinguish the two stable states (I and V) using a single bit that is associated with every block of memory. Few blocks are ever in transient states, and those states can be maintained with a small dedicated structure. This design is a subset of the more complete first design, with minimal storage cost.

Zero-bit logical OR. To avoid having to modify memory, we can have the caches reconstruct the memory state on-demand. The memory state of a block is a function of the block’s state in every cache, so, if all of the caches aggregate their state, they can determine the memory state. The system can infer whether the memory is the owner of a block by having all of the cores send an “IsOwned?”¹ signal to a logical OR gate (or tree of OR gates) with a number of inputs equal to the number of caches. If the output of this OR is high, it denotes that a cache is owner; if the output is low, then memory is the owner. This solution avoids the need for any state to be maintained in memory. However, implementing a fast OR, either with logic gates or a wired-OR, can be difficult.

¹This IsOwned signal is not to be confused with the Owned cache state. The IsOwned signal is asserted by a cache in a state of ownership, which includes the Owned, Modified, and Exclusive cache states.

TABLE 6.4: Common Transactions.

Transaction	Goal of Requestor
GetShared (GetS)	obtain block in Shared (read-only) state
GetModified (GetM)	obtain block in Modified (read-write) state
Upgrade (Upg)	upgrade block state from read-only (Shared or Owned) to read-write (Modified); Upg (unlike GetM) does not require data to be sent to requestor
PutShared (PutS)	evict block in Shared state ^a
PutExclusive (PutE)	evict block in Exclusive state ^a
PutOwned (PutO)	evict block in Owned state
PutModified (PutM)	evict block in Modified state

- a. Some protocols do not require a coherence transaction to evict a Shared block and/or an Exclusive block (i.e., the PutS and/or PutE are “silent”).

Although most protocols use a similar set of transactions, they differ quite a bit in how the coherence controllers interact to perform the transactions. As we will see in the next section, in some protocols (e.g., snooping protocols) a cache controller initiates a GetS transaction by broadcasting a GetS request to all coherence controllers in the system, and whichever controller is currently the owner of the block responds to the requestor with a message that contains the desired data. Conversely, in other protocols (e.g., directory protocols) a cache controller initiates a GetS transaction by sending a unicast GetS message to a specific, pre-defined coherence controller that may either respond directly or may forward the request to another coherence controller that will respond to the requestor.

TABLE 6.5: Common Core Requests to Cache Controller.

Event	Response of (Typical) Cache Controller
load	if cache hit, respond with data from cache; else initiate GetS transaction
store	if cache hit in state E or M, write data into cache; else initiate GetM or Upg transaction
atomic read-modify-write	if cache hit in state E or M, atomically execute read-modify-write semantics; else initiate GetM or Upg transaction
instruction fetch	if cache hit (in I-cache), respond with instruction from cache; else initiate GetS transaction
read-only prefetch	if cache hit, ignore; else may optionally initiate GetS transaction ^a
read-write prefetch	if cache hit in state M, ignore; else may optionally initiate GetM or Upg transaction
replacement	depending on state of block, initiate PutS, PutE, PutO, or PutM transaction

- a. A cache controller may choose to ignore a prefetch request from the core.

6.4.3 Major Protocol Design Options

There are many different ways to design a coherence protocol. Even for the same set of states and transactions, there are many different possible protocols. The design of the protocol determines what events and transitions are possible at each coherence controller; unlike with states and transactions, there is no way to present a list of possible events or transitions that is independent from the protocol.

Despite the enormous design space for coherence protocols, there are two primary design decisions that have a major impact on the rest of the protocol, and we discuss them next.

6.4.3.1 Snooping vs. Directory

There are two main classes of coherence protocols: snooping and directory. We present a brief overview of these protocols now and defer in-depth coverage of them until Chapter 7 and Chapter 8, respectively.

- Snooping protocol: A cache controller initiates a request for a block by broadcasting a request message to all other coherence controllers. The coherence controllers collectively “do the right thing,” e.g., sending data in response to another core’s request if they are the owner. Snooping protocols rely on the interconnection network to deliver the broadcast messages in a consistent order to all cores. Most snooping protocols assume that requests arrive in a total order, e.g., via a shared-wire bus, but more advanced interconnection networks and relaxed orders are possible.
- Directory protocol: A cache controller initiates a request for a block by unicasting it to the memory controller that is the *home* for that block. Each memory controller maintains a directory that holds state about each block in the LLC/memory, such as the identity of the current owner or the identities of current sharers. When a request for a block reaches the home, the memory controller looks up this block’s directory state. For example, if the request is a GetS, the memory controller looks up the directory state to determine the owner. If the LLC/memory is the owner, the memory controller completes the transaction by sending a data response to the requestor. If a cache controller is the owner, the memory controller forwards the request to the owner cache; when the owner cache receives the forwarded request, it completes the transaction by sending a data response to the requestor.

The choice of snooping versus directory involves making tradeoffs. Snooping protocols are logically simple, but they do not scale to large numbers of cores because broadcasting does not scale.

Directory protocols are scalable because they unicast, but many transactions take more time because they require an extra message to be sent when the home is not the owner. In addition, the choice of protocol affects the interconnection network (e.g., classical snooping protocols require a total order for request messages).

6.4.3.2 Invalidate vs. Update

The other major design decision in a coherence protocol is to decide what to do when a core writes to a block. This decision is independent of whether the protocol is snooping or directory. There are two options:

- Invalidate protocol: When a core wishes to write to a block, it initiates a coherence transaction to invalidate the copies in all other caches. Once the copies are invalidated, the requestor can write to the block without the possibility of another core reading the block's old value. If another core wishes to read the block after its copy has been invalidated, it has to initiate a new coherence transaction to obtain the block, and it will obtain a copy from the core that wrote it, thus preserving coherence.
- Update protocol: When a core wishes to write a block, it initiates a coherence transaction to update the copies in all other caches to reflect the new value it wrote to the block.

Once again, there are tradeoffs involved in making this decision. Update protocols reduce the latency for a core to read a newly written block because the core does not need to initiate and wait for a GetS transaction to complete. However, update protocols typically consume substantially more bandwidth than invalidate protocols because update messages are larger than invalidate messages (an address and a new value, rather than just an address). Furthermore, update protocols greatly complicate the implementation of many memory consistency models. For example, preserving write atomicity (Section 5.5) becomes much more difficult when multiple caches must apply multiple updates to multiple copies of a block. Because of the complexity of update protocols, they are rarely implemented; in this primer, we focus on the far more common invalidate protocols.

6.4.3.3 Hybrid Designs

For both major design decisions, one option is to develop a hybrid. There are protocols that combine aspects of snooping and directory protocols [6, 2], and there are protocols that combine aspects of invalidate and update protocols [8]. The design space is rich and architects are not constrained to following any particular style of design.

. . . .

CHAPTER 7

Snooping Coherence Protocols

In this chapter, we present snooping coherence protocols. Snooping protocols were the first widely-deployed class of protocols and they continue to be used in a variety of systems. Snooping protocols offer many attractive features, including low-latency coherence transactions and a conceptually simpler design than the alternative, directory protocols (Chapter 8).

We first introduce snooping protocols at a high level (Section 7.1). We then present a simple system with a complete but unsophisticated three-state (MSI) snooping protocol (Section 7.2). This system and protocol serve as a baseline upon which we later add system features and protocol optimizations. The protocol optimizations that we discuss include the additions of the Exclusive state (Section 7.3) and the Owned state (Section 7.4), as well as higher performance interconnection networks (Sections 7.5 and 7.6). We then discuss commercial systems with snooping protocols (Section 7.7) before concluding the chapter with a discussion of snooping and its future (Section 7.8).

Given that some readers may not wish to delve too deeply into snooping, we have organized the chapter such that readers may skim or skip Sections 7.3 through 7.6, if they so choose.

7.1 INTRODUCTION TO SNOOPING

Snooping protocols are based on one idea: all coherence controllers observe (*snoop*) coherence requests in the same order and collectively “do the right thing” to maintain coherence. By requiring that all requests to a given block arrive in order, a snooping system enables the distributed coherence controllers to correctly update the finite state machines that collectively represent a cache block’s state.

Traditional snooping protocols broadcast requests to all coherence controllers, including the controller that initiated the request. The coherence requests typically travel on an ordered broadcast network, such as a bus. The ordered broadcast ensures that every coherence controller observes the same series of coherence requests in the same order, i.e., that there is a total order of coherence requests. Since a total order subsumes all per-block orders, this total order guarantees that all coherence controllers can correctly update a cache block’s state.

TABLE 7.1: Snooping Coherence Example. All Activity Involves Block A (Denoted “A:”)

time	Core C1	Core C2	LLC/Memory
0	A:I	A:I	A:I (LLC/memory is owner)
1	A:GetM from Core C1 / M	A:GetM from Core C1 / I	A:GetM from Core C1 / M (LLC/memory is not owner)
2	A:GetM from Core C2 / I	A:GetM from Core C2 / M	A: GetM from Core C2 / M

To illustrate the importance of processing coherence requests in the same per-block order, consider the examples in Tables 7.1 and 7.2 where both core C1 and core C2 want to get the same block A in state M. In Table 7.1, all three coherence controllers observe the same per-block order of coherence requests and collectively maintain the single-writer–multiple-reader (SWMR) invariant. Ownership of the block progresses from the LLC/memory to core C1 to core C2. Every coherence controller independently arrives at the correct conclusion about the block’s state as a result of each observed request. Conversely, Table 7.2 illustrates how incoherence might arise if core C2 observes a different per-block order of requests than core C1 and the LLC/memory. First, we have a situation in which both core C1 and core C2 are simultaneously in state M, which violates the SWMR invariant. Next, we have a situation in which no coherence controller believes it is the owner and thus a coherence request at this time would not receive a response (perhaps resulting in deadlock).

Traditional snooping protocols create a total order of coherence requests across *all blocks*, even though coherence requires only a per-block order of requests. Having a total order makes it easier

TABLE 7.2: Snooping (In)Coherence Example. All Activity Involves Block A (Denoted “A:”)

time	Core C1	Core C2	LLC/Memory
0	A:I	A:I	A:I (LLC/memory is owner)
1	A: GetM from Core C1 / M	A: GetM from Core C2 / M	A: GetM from Core C1 / M (LLC/memory is not owner)
2	A: GetM from Core C2 / I	A: GetM from Core C1 / I	A: GetM from Core C2 / M

TABLE 7.3: Per-block Order, Coherence, and Consistency. States and Operations that Pertain to Address A are Preceded by the Prefix “A:”, and we Denote a Block A in State X with Value V as “A:X[V]”. If the Value is Stale, We Omit It (e.g., “A:I”).

time	Core C1	Core C2	LLC/Memory
0	A:I B:M[0]	A:S[0] B:I	A:S[0] B:M

3	A:M[1] B:GetS from Core C2 / S[1]	A:S[0] B:I	A:M B:GetS from Core C2 / S[1]
4	A:M[1] B:S[1]	A:S[0] B:GetS from Core C2/S[1] r1 = B[1]	A:M B:S[1]
5	A:M[1] B:S[1]	A:S[0] r2 = A[0] B:S[1]	A:M B:S[1]
6	A:M[1] B:S[1]	A: GetM from Core1 / I B:S[1]	A:M B:S[1]
r1 = 1, r2 = 0 violates SC and TSO			

to implement memory consistency models that require a total order of memory references, such as SC and TSO. Consider the example in Table 7.3 which involves two blocks A and B; each block is requested exactly once and so the system trivially observes per-block request orders. Yet because cores C1 and C2 observe the GetM and GetS requests out-of-order, this execution violates both the SC and TSO memory consistency models.

Sidebar: How Snooping Depends on a Total Order of Coherence Requests

At first glance, the reader may assume that the problem in Table 7.3 arises because the SWMR invariant is violated for block A in cycle 1, since C1 has an M copy and C2 still has an S copy. However, Table 7.4 illustrates the same example, but enforces a total order of coherence requests. This example is identical until cycle 4, and thus has the same apparent SWMR violation. However, like the proverbial “tree in the forest,” this violation does not cause a problem because it is not observed (i.e., there is “no one there to hear it”). Specifically, because the cores see both requests in the same order, C2 invalidates block A before it can see the new value for block B. Thus when C2 reads block A, it must get the new value and therefore yields a correct SC and TSO execution.

Traditional snooping protocols use the total order of coherence requests to determine when, in a logical time based on snoop order, a particular request has been observed. In the example of Table 7.4, because of the total order, core C1 can infer that C2 will see the GetM for A before the GetS for B, and thus C2 does not need to send a specific acknowledgement message when it receives the coherence message. This implicit acknowledgment of request reception distinguishes snooping protocols from the directory protocols we study in the next chapter.

TABLE 7.4. Total Order, Coherence, and Consistency. States and Operations that Pertain to Address A are Preceded by the Prefix “A:”, and we Denote a Block A in State X with Value V as “A:X[V]”. If the Value is Stale, We Omit It (e.g., “A:I”).

time	Core C1	Core C2	LLC/Memory
0	A:I B:M[0]	A:S[0] B:I	A:S[0] B:M
1	A: GetM from Core C1 / M[0] store A = 1 B:M[0]	A:S[0] B:I	A:S[0] B:M
2	A:M[1] store B = 1 B:M[1]	A:S[0] B:I	A: GetM from Core C1 / M B:M
3	A:M[1] B: GetS from Core C2 / S[1]	A:S[0] B:I	A:M B: GetS from Core C2 / S[1]
4	A:M[1] B:S[1]	A: GetM from Core1 / I B:I	A:M B:S[1]
5	A:M[1] B:S[1]	A:I B: GetS from Core C2/S[1] r1 = B[1]	A:M B:S[1]
6	A: GetS from Core C2/S[1] B:S[1]	A: GetS from Core C2/S[1] r2 = A[1] B:S[1]	A: GetS from Core C2 / S[1] B:S[1]

r1 = 1, r2 = 1 satisfies SC and TSO

We discuss some of the subtler issues regarding the need for a total order in the sidebar.

Requiring that broadcast coherence requests be observed in a total order has important implications for the interconnection network used to implement traditional snooping protocols. Because many coherence controllers may simultaneously attempt to issue coherence requests, the interconnection network must serialize these requests into some total order. However the network determines this order, this mechanism becomes known as the protocol's *serialization (ordering) point*. In the general case, a coherence controller issues a coherence request, the network orders that request at the serialization point and broadcasts it to all controllers, and the issuing controller learns where its request has been ordered by snooping the stream of requests it receives from the controller. As a concrete and simple example, consider a system which uses a bus to broadcast coherence requests. Coherence controllers must use arbitration logic to ensure that only a single request is issued on the bus at once. This arbitration logic acts as the serialization point because it effectively determines the order in which requests appear on the bus. A subtle but important point is that a coherence request is ordered the instant the arbitration logic serializes it, but a controller may only be able to determine this order by snooping the bus to observe which other requests appear before and after its own request. Thus, coherence controllers may observe the total request order several cycles after the serialization point determines it.

Thus far, we have discussed only coherence requests, but not the responses to these requests. The reason for this seeming oversight is that the key aspects of snooping protocols revolve around the requests. There are few constraints on response messages. They can travel on a separate interconnection network that does not need to support broadcast nor have any ordering requirements. Because response messages carry data and are thus much longer than requests, there are significant benefits to being able to send them on a simpler, lower-cost network. Notably, response messages do not affect the serialization of coherence transactions. Logically, a coherence transaction—which consists of a broadcast request and a unicast response—occurs when the request is ordered, *regardless of when the response arrives at the requestor*. The time interval between when the request appears on the bus and when the response arrives at the requestor does affect the implementation of the protocol (e.g., during this gap, are other controllers allowed to request this block? If so, how does the requestor respond?), but it does not affect the serialization of the transaction.¹

7.2 BASELINE SNOOPING PROTOCOL

In this section, we present a straightforward, unoptimized snooping protocol and describe its implementation on two different system models. The first, simple system model illustrates the basic

¹This logical serialization of coherence transactions is analogous to the logical serialization of instruction execution in processor cores. Even when a core performs out-of-order execution, it still commits (serializes) instructions in program order.

approach for implementing snooping coherence protocols. The second, modestly more complex baseline system model illustrates how even relatively simple performance improvements may impact coherence protocol complexity. These examples provide insight into the key features of snooping protocols while revealing inefficiencies that motivate the features and optimizations presented in subsequent sections of this chapter. Sections 7.5 and 7.6 discuss how to adapt this baseline protocol for more advanced system models.

7.2.1 High-Level Protocol Specification

The baseline protocol has only three stable states: M, S, and I. Such a protocol is typically referred to as an MSI protocol. Like the protocol in Section 6.3, this protocol assumes a write-back cache. A block is owned by the LLC/memory unless the block is in a cache in state M. Before presenting the detailed specification, we first illustrate a higher level abstraction of the protocol in order to understand its fundamental behaviors. In Figures 7.1 and 7.2, we show the transitions between the stable states at the cache and memory controllers, respectively.

There are three notational issues to be aware of. First, in Figure 7.1, the arcs are labeled with coherence requests that are observed on the bus. We intentionally omit other events, including loads, stores, and coherence responses. Second, the coherence events at the cache controller are labeled with either “Own” or “Other” to denote whether the cache controller observing the request is the requestor or not. Third, in Figure 7.2, we specify the state of a block at memory using a cache-centric notation (e.g., a memory state of M denotes that there exists a cache with the block in state M).

7.2.2 Simple Snooping System Model: Atomic Requests, Atomic Transactions

Figure 7.3 illustrates the simple system model, which is nearly identical to the baseline system model introduced in Figure 2.1. The only difference is that the generic interconnection network from Figure 2.1 has been specified as a bus. Each core can issue load and store requests to its cache controller; the cache controller will choose a block to evict when it needs to make room for another block. The bus facilitates a total order of coherence requests that are snooped by all coherence controllers. Like the example in the previous chapter, this system model has atomicity properties that simplify the coherence protocol. Specifically, this system implements two atomicity properties which we define as *Atomic Requests* and *Atomic Transactions*. The *Atomic Requests* property states that a coherence request is ordered in the same cycle that it is issued. This property eliminates the possibility of a block’s state changing—due to another core’s coherence request—between when a request is issued and when it is ordered. The *Atomic Transactions* property states that coherence transactions are *atomic* in that a subsequent request for the *same* block may not appear on the bus until after the first transaction completes (i.e., until after the response has appeared on the bus). Because coherence involves operations on a single block, whether or not the system permits subsequent requests

FIGURE 7.1: MSI: Transitions between stable states at cache controller.

FIGURE 7.2: MSI: Transitions between stable states at memory controller.

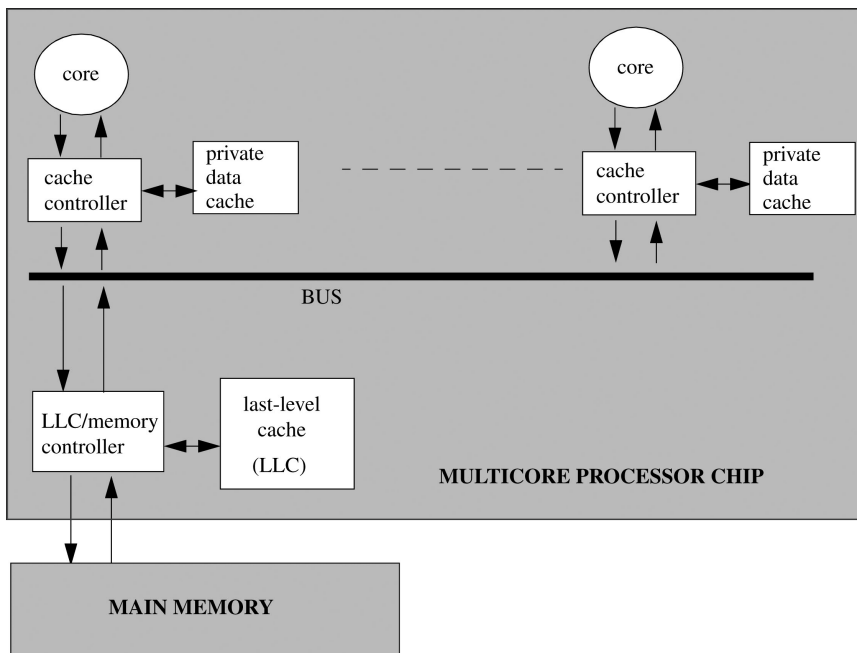

FIGURE 7.3: Simple snooping system mode.

to *different* blocks does not impact the protocol. Although simpler than most current systems, this system model resembles the SGI Challenge, a successful machine in the 1980s [5].

7.2.2.1 Detailed Protocol Specification

Tables 7.5 and 7.6 present the detailed coherence protocol for the simple system model. Compared to the high-level description in Section 7.2.1, the most significant difference is the addition of two transient states in the cache controller and one in the memory controller. This protocol has very few transient states because the atomicity constraints of the simple system model greatly limit the number of possible message interleavings.

Flashback to Quiz Question 6: In an MSI snooping protocol, a cache block may only be in one of three coherence states. *True or false?*

Answer: *False!* Even for the simplest system model, there are more than three states, because of transient states.

Shaded entries in the table denote impossible (or at least erroneous) transitions. For example, a cache controller should never receive a *Data* message for a block that it has not requested (i.e., a block in state I in its cache). Similarly, the *Atomic Transactions* constraint prevents another core from issuing a subsequent request before the current transaction completes; the table entries labeled “(A)” cannot occur due to this constraint. Blank entries denote legal transitions that require no action. These tables omit many implementation details that are not necessary for understanding the protocol. Also, in this protocol and the rest of the protocols in this chapter, we omit the event corresponding to *Data* for another core’s transaction; a core never takes any action in response to observing *Data* on the bus for another core’s transaction.

As with all MSI protocols, loads may be performed (i.e., hit) in states S and M, while stores hit only in state M. On load and store misses, the cache controller initiates coherence transactions by sending *GetS* and *GetM* requests, respectively.² The transient states IS^D , IM^D , and SM^D indicate that the request message has been sent, but the data response (*Data*) has not yet been received. In these transient states, because the requests have already been ordered, the transactions have already been ordered and the block is *logically* in state S, M, or M, respectively. A load or store must

²We do not include an *Upgrade* transaction in this protocol, which would optimize the S-to-M transition by not needlessly sending data to the requestor. Adding an *Upgrade* would be fairly straightforward for this system model with *Atomic Requests*, but it is significantly more complicated without *Atomic Requests*. We discuss this issue when we present a protocol without *Atomic Requests*.

TABLE 7.5: Simple Snooping (Atomic Requests, Atomic Transactions): Cache Controller

States	Processor Core Events			Bus Events						
				Own Transaction				Transactions For Other Cores		
	Load	Store	Replacement	Own-GetS	Own-GetM	Own-PutM	Data	Other-GetS	Other-GetM	Other-PutM
I	issue GetS /IS ^D	issue GetM /IM ^D								
IS ^D	stall Load	stall Store	stall Evict				copy data into cache, load hit /S	(A)	(A)	(A)
IM ^D	stall Load	stall Store	stall Evict				copy data into cache, store hit /M	(A)	(A)	(A)
S	load hit	issue GetM /SM ^D	-/I						-/I	
SM ^D	load hit	stall Store	stall Evict				copy data into cache, store hit /M	(A)	(A)	(A)
M	load hit	store hit	issue PutM, send Data to memory /I					send Data to req and memory /S	send Data to req /I	

TABLE 7.6: Simple Snooping (Atomic Requests, Atomic Transactions): Memory Controller

State	Bus Events			
	GetS	GetM	PutM	Data from Owner
IorS	send data block in Data message to requestor/IorS	send data block in Data message to requestor/M		
IorS ^D	(A)	(A)		update data block in memory/IorS
M	-/IorS ^D		-/IorS ^D	

wait for the Data to arrive, though.³ Once the data response appears on the bus, the cache controller can copy the data block into the cache, transition to stable state S or M, as appropriate, and perform the pending load or store.

The system model's atomicity properties simplify cache miss handling in two ways. First, the *Atomic Requests* property ensures that when a cache controller seeks to upgrade permissions to a block—to go from I to S, I to M, or S to M—it can issue a request without worrying that another core's request might be ordered ahead of its own. Thus, the cache controller can transition immediately to state IS^D, IM^D, or SM^D, as appropriate, to wait for a data response. Similarly, the *Atomic Transactions* property ensures that no subsequent requests for a block will occur until after the current transaction completes, eliminating the need to handle requests from other cores while in one of these transient states.

A data response may come from either the memory controller or another cache that has the block in state M. A cache that has a block in state S can ignore GetS requests because the memory controller is required to respond, but must invalidate the block on GetM requests to enforce the coherence invariant. A cache that has a block in state M must respond to both GetS and GetM requests, sending a data response and transitioning to state S or state I, respectively.

The LLC/memory has two stable states, M and IorS, and one transient state IorS^D. In state IorS, the memory controller is the owner and responds to both GetS and GetM requests because this state indicates that no cache has the block in state M. In state M, the memory controller does not respond with data because the cache in state M is the owner and has the most recent copy of the data. However, a GetS in state M means that the cache controller will transition to state S, so the memory controller must also get the data, update memory, and begin responding to all future requests. It does this by transitioning immediately to the transient state IorS^D and waits until it receives the data from the cache that owns it.

When the cache controller evicts a block due to a replacement decision, this leads to the protocol's two possible coherence downgrades: from S to I and from M to I. In this protocol, the S-to-I downgrade is performed “silently” in that the block is evicted from the cache without any communication with the other coherence controllers. In general, silent state transitions are possible only when all other coherence controllers' behavior remains unchanged; for example, a silent eviction of an owned block is not allowable. The M-to-I downgrade requires communication because the M copy of the block is the only valid copy in the system and cannot simply be discarded. Thus, another coherence controller (i.e., the memory controller) must change its state. To replace a block in state M, the cache controller issues a PutM request on the bus and then sends the data back to the memory controller. At the LLC, the block enters state IorS^D when the PutM request arrives, then

³Technically, a store may be performed as soon as the request is ordered, so long as the newly stored value is not overwritten when the Data arrives. Similarly, a subsequent load to a newly written value is permitted.

transitions to state IorS when the Data message arrives.⁴ The *Atomic Requests* property simplifies the cache controller, by preventing an intervening request that might downgrade the state (e.g., another core's GetM request) before the PutM gets ordered on the bus. Similarly, the *Atomic Transactions* property simplifies the memory controller by preventing other requests for the block until the PutM transaction completes and the memory controller is ready to respond to them.

7.2.2.2 Running Example

In this section, we present an example execution of the system to show how the coherence protocol behaves in a common scenario. We will use this example in subsequent sections both to understand the protocols and also to highlight differences between them. The example includes activity for just one block, and initially, the block is in state I in all caches and in state IorS at the LLC/memory.

In this example, illustrated in Table 7.7, cores C1 and C2 issue load and store instructions, respectively, that miss on the same block. core C1 attempts to issue a GetS and core C2 attempts to issue a GetM. We assume that core C1's request happens to get serialized first and the *Atomic Transactions* property prevents core C2's request from reaching the bus until C1's request completes. The memory controller responds to C1 to complete the transaction on cycle 3. Then, core C2's GetM is serialized on the bus; C1 invalidates its copy and the memory controller responds to C2 to complete that transaction. Lastly, C1 issues another GetS. C2, the owner, responds with the data and changes its state to S. C2 also sends a copy of the data to the memory controller because the LLC/memory is now the owner and needs an up-to-date copy of the block. At the end of this execution, C1 and C2 are in state S and the LLC/memory is in state IorS.

7.2.3 Baseline Snooping System Model: Non-Atomic Requests, Atomic Transactions

The baseline snooping system model, which we use for most of the rest of this chapter, differs from the simple snooping system model by permitting non-atomic requests. Non-atomic requests arise from a number of implementation optimizations, but most commonly due to inserting a message queue (or even a single buffer) between the cache controller and the bus. By separating when a request is issued from when it is ordered, the protocol must address a window of vulnerability that did not exist in the simple snooping system. The baseline snooping system model preserves the *Atomic Transactions* property, which we do not relax until Section 7.5.

We present the detailed protocol specification, including all transient states, in Tables 7.8 and 7.9. Compared to the protocol for the simple snooping system in Section 7.2.2, the most significant difference is the much larger number of transient states. Relaxing the *Atomic Requests* property

⁴We make the simplifying assumption that these messages cannot arrive out of order at the memory controller.

TABLE 7.7: Simple Snooping: Example Execution. All Activity is for One Block.

cycle	Core C1	Core C2	LLC/memory	request on bus	data on bus
Initial	I	I	IorS		
1	load miss; issue GetS / IS ^D				
2				GetS (C1)	
3		store miss; stall due to <i>Atomic Transactions</i>	send response to C1		
4					data from LLC/mem
5	copy data to cache; perform load / S	issue GetM / IM ^D			
6				GetM (C2)	
7	- / I		send response to C2 / M		
8					data from LLC/mem
9		copy data to cache; perform store / M			
10	load miss; issue GetS / IS ^D				
11				GetS (C1)	
12		send data to C1 and to LLC/mem / S	- / IorS ^D		
13					data from C2
14	copy data from C2; perform load / S		copy data from C2 / IorS		

introduces numerous situations in which a cache controller observes a request from another controller on the bus in between issuing its coherence request and observing its own coherence request on the bus.

Taking the I-to-S transition as an example, the cache controller issues a GetS request and changes the block's state from I to IS^{AD}. Until the requesting cache controller's own GetS is observed on the bus and serialized, the block's state is *effectively* I. That is, the requestor's block is treated as if it were in I; loads and stores cannot be performed and coherence requests from other nodes must be ignored. Once the requestor observes its own GetS, the request is ordered and block is logically S, but loads cannot be performed because the data has not yet arrived. The cache controller changes the block's state to IS^D and waits for the data response from the previous owner. Because

TABLE 7.8: MSI Snooping Protocol with Atomic Transactions-Cache Controller. A Shaded Entry Labeled “(A)” Denotes that this Transition is Impossible Because Transactions are Atomic on Bus.

M	hit	hit	issue PutM/MI ^A				send data to requestor and to memory/S	send data to requestor/I	-	
MI ^A	hit	hit	stall			send data to memory/I	send data to requestor and to memory/II ^A	send data to requestor/II ^A		
II ^A	stall	stall	stall			send NoData to memory/I	-	-		

TABLE 7.9: MSI Snooping Protocol with Atomic Transactions - Memory Controller. A Shaded Entry Labeled “(A)” Denotes that this Transition is Impossible Because Transactions are Atomic on Bus.

	GetS	GetM	PutM	Data From Owner	NoData
IorS	send data to requestor	send data to requestor/M	-/IorS ^D		
IorS ^D	(A)	(A)		write data to LLC/memory /IorS	-/IorS
M	-/IorS ^D		-/M ^D		
M ^D	(A)	(A)		write data to LLC/IorS	-/M

of the *Atomic Transactions* property, the data message is the next coherence message (to the same block). Once the data response arrives, the transaction is complete and the requestor changes the block's state to the stable S state and performs the load. The I-to-M transition proceeds similarly to this I-to-S transition.

The transition from S to M illustrates the potential for state changes to occur during the window of vulnerability. If a core attempts to store to a block in state S, the cache controller issues a GetM request and transitions to state SM^{AD} . The block remains effectively in state S, so loads may continue to hit and the controller ignores GetS requests from other cores. However, if another core's GetM request gets ordered first, the cache controller must transition the state to IM^{AD} to prevent further load hits. The window of vulnerability during the S-to-M transition complicates the addition of an Upgrade transaction, as we discuss in the sidebar.

Sidebar: Upgrade Transactions in Systems Without Atomic Requests

For the protocol with *Atomic Requests*, an Upgrade transaction is an efficient way for a cache to transition from Shared to Modified. The Upgrade request invalidates all shared copies, and it is much faster than issuing a GetM, because the requestor needs to wait only until the Upgrade is serialized (i.e., the bus arbitration latency) rather than wait for data to arrive from the LLC/memory.

However, without *Atomic Requests*, adding an Upgrade transaction becomes more difficult because of the window of vulnerability between issuing a request and when the request is serialized. The requestor may lose its shared copy due to an Other-GetM or Other-Upgrade that is serialized during this window of vulnerability. The simplest solution to this problem is to change the block's state to a new state in which it waits for its own Upgrade to be serialized. When its Upgrade is serialized, which will invalidate other S copies (if any) but will not return data, the core must then issue a subsequent GetM request to transition to M.

Handling Upgrades more efficiently is difficult, because the LLC/memory needs to know when to send data. Consider the case in which cores C0 and C2 have a block A shared and both seek to upgrade it and, at the same time, core C1 seeks to read it. C0 and C2 issue Upgrade requests and C1 issues a GetS request. Suppose they serialize on the bus as C0, C1, and C2. C0's Upgrade succeeds, so the LLC/memory (in state IorS) should change its state to M but not send any data, and C2 should invalidate its S copy. C1's GetS finds the block in state M at C0, which responds with the new data value and updates the LLC/memory back to state IorS. C2's Upgrade finally appears, but because it has lost its shared copy, it needs the LLC/memory to respond. Unfortunately, the LLC/memory is in state IorS and cannot tell that this Upgrade needs data. Alternatives exist to solve this issue, but are outside the scope of this primer.

The window of vulnerability also affects the M-to-I coherence downgrade, in a much more significant way. To replace a block in state M, the cache controller issues a PutM request and changes the block state to MI^A , unlike the protocol in Section 7.2.2, it does not immediately send the data to the memory controller. Until the PutM is observed on the bus, the block's state is effectively M and the cache controller must respond to other cores' coherence requests for the block. In the case where no intervening coherence requests arrive, the cache controller responds to observing its own PutM by sending the data to the memory controller and changing the block state to state I. If an intervening GetS or GetM request arrives before the PutM is ordered, the cache controller must respond as if it were in state M and then transition to state II^A to wait for its PutM to appear on the bus. Intuitively, the cache controller should simply transition to state I once it sees its PutM because it has already given up ownership of the block. Unfortunately, doing so will leave the memory controller stuck in a transient state because it also receives the PutM request. Nor can the cache controller simply send the data anyway because doing so might overwrite valid data.⁵ The solution is for the cache controller to send a special NoData message to the memory controller when it sees its PutM while in state II^A . The memory controller is further complicated by needing to know which stable state it should return to if it receives a NoData message. We solve this problem by adding a second transient memory state M^D . Note that these transient states represent an exception to our usual transient state naming convention. In this case, state X^D indicates that the memory controller should revert to state X when it receives a NoData message (and move to state IorS if it receives a data message).

7.2.4 Running Example

Returning to the running example, illustrated in Table 7.10, core C1 issues a GetS and core C2 issues a GetM. Unlike the previous example (in Table 7.7), eliminating the *Atomic Requests* property means that both cores issue their requests and change their state. We assume that core C1's request happens to get serialized first, and the *Atomic Transactions* property ensures that C2's request does not appear on the bus until C1's transaction completes. After the LLC/memory responds to complete C1's transaction, core C2's GetM is serialized on the bus. C1 invalidates its copy and the LLC/memory responds to C2 to complete that transaction. Lastly, C1 issues another GetS. When this GetS reaches the bus, C2, the owner, responds with the data and changes its state to S. C2 also sends a copy of the data to the memory controller because the LLC/memory is now the owner and

⁵ Consider the case in which core C1 has a block in M and issues a PutM, but core C2 does a GetM and core C3 does a GetS, both of which are ordered before C1's PutM. C2 gets the block in M, modifies the block, and then in response to C3's GetS, updates the LLC/memory with the updated block. When C1's PutM is finally ordered, writing the data back would overwrite C2's update.

TABLE 7.10: Baseline Snooping: Example Execution.

cycle	Core C1	Core C2	LLC/memory	request on bus	data on bus
1	issue GetS / IS ^{AD}				
2		issue GetM / IM ^{AD}			
3				GetS (C1)	
4	- / IS ^D		send data to C1 / IorS		
5					data from LLC/mem
6	copy data from LLC/mem / S			GetM (C2)	
7	- / I	- / IM ^D	send data to C2 / M		
8					data from LLC/mem
9		copy data from LLC/mem / M			
10	issue GetS / IS ^{AD}				
11				GetS (C1)	
12	- / IS ^D	send data to C1 and to LLC/mem / S	- / IorS ^D		
13					data from C2
14	copy data from C2 / S		copy data from C2 / IorS		

needs an up-to-date copy of the block. At the end of this execution, C1 and C2 are in state S and the LLC/memory is in state IorS.

7.2.5 Protocol Simplifications

This protocol is relatively straightforward and sacrifices performance to achieve this simplicity. The most significant simplification is the use of atomic transactions on the bus. Having atomic transactions eliminates many possible transitions, denoted by “(A)” in the tables. For example, when a core has a cache block in state IM^D, it is not possible for that core to observe a coherence request for that block from another core. If transactions were not atomic, such events could occur and would force us to redesign the protocol to handle them, as we show in Section 7.5.

Another notable simplification that sacrifices performance involves the event of a store request to a cache block in state S. In this protocol, the cache controller issues a GetM and changes the block state to SM^{AD}. A higher performance but more complex solution would use an upgrade transaction, as discussed in the earlier sidebar.

7.3 ADDING THE EXCLUSIVE STATE

There are many important protocol optimizations, which we discuss in the next several sections. More casual readers may want to skip or skim these sections on first reading. One very commonly used optimization is to add the Exclusive (E) state, and in this section, we describe how to create a MESI snooping protocol by augmenting the baseline protocol from Section 7.2.3 with the E state. Recall from Chapter 2 that if a cache has a block in the Exclusive state, then the block is valid, read-only, clean, exclusive (not cached elsewhere), and owned. A cache controller may silently change a cache block's state from E to M without issuing a coherence request.

7.3.1 Motivation

The Exclusive state is used in almost all commercial coherence protocols because it optimizes a common case. Compared to an MSI protocol, a MESI protocol offers an important advantage in the situation in which a core first reads a block and then subsequently writes it. This is a typical sequence of events in many important applications, including single-threaded applications. In an MSI protocol, on a load miss, the cache controller will initiate a GetS transaction to obtain read permission; on the subsequent store, it will then initiate a GetM transaction to obtain write permission. However, a MESI protocol enables the cache controller to obtain the block in state E, instead of S, in the case that the GetS occurs when no other cache has access to the block. Thus, a subsequent store does not require the GetM transaction; the cache controller can silently upgrade the block's state from E to M and allow the core to write to the block. The E state can thus eliminate half of the coherence transactions in this common scenario.

7.3.2 Getting to the Exclusive State

Before explaining how the protocol works, we must first figure out how the issuer of a GetS determines that there are no other sharers and thus that it is safe to go directly to state E instead of state S. There are at least two possible solutions:

- Adding a wired-OR “sharer” signal to bus: when the GetS is ordered on the bus, all cache controllers that share the block assert the “sharer” signal. If the requestor of the GetS observes that the “sharer” signal is asserted, the requestor changes its block state to S; else, the requestor changes its block state to E. The drawback to this solution is having to implement the wired-OR signal. This additional shared wire might not be problematic in this baseline snooping system model that already has a shared wire bus, but it would greatly complicate implementations that do not use shared wire buses (Section 7.6).
- Maintaining extra state at the LLC: an alternative solution is for the LLC to distinguish between states I (no sharers) and S (one or more sharers), which was not needed for the

MSI protocols. In state I, the memory controller responds with data that is specially labeled as being Exclusive; in state S, the memory controller responds with data that is unlabeled. However, maintaining the S state exactly is challenging, since the LLC must detect when the last sharer relinquishes its copy. First, this requires that a cache controller issues a PutS message when it evicts a block in state S. Second, the memory controller must maintain a count of the sharers as part of the state for that block. This is much more complex and bandwidth intensive than our previous protocols, which allowed for silent evictions of blocks in S. A simpler, but less complete, alternative allows the LLC to conservatively track sharers; that is, the memory controller's state S means that there are zero-or-more caches in state S. The cache controller silently replaces blocks in state S, and thus the LLC stays in S even after the last sharer has been replaced. If a block in state M is written back (with a PutM), the state of the LLC block becomes I. This "conservative S" solution forgoes some opportunities to use the E state (i.e., when the last sharer replaces its copy before another core issues a GetM), but it avoids the need for explicit PutS transactions and still captures many important sharing patterns.

In the MESI protocol we present in this section, we choose the most implementable option—maintaining a conservative S state at the LLC—to both avoid the engineering problems associated with implementing wired-OR signals in high-speed buses and avoid explicit PutS transactions.

7.3.3 High-Level Specification of Protocol

In Figures 7.4 and 7.5, we show the transitions between stable states in the MESI protocol. The MESI protocol differs from the baseline MSI protocol at both the cache and LLC/memory. At the cache, a GetS request transitions to S or E, depending upon the state at the LLC/memory when the GetS is ordered. Then, from state E, the block can be silently changed to M. In this protocol, we use a PutM to evict a block in E, instead of using a separate PutE; this decision helps keep the protocol specification concise, and it has no impact on the protocol functionality.

The LLC/memory has one more stable state than in the MSI protocol. The LLC/memory must now distinguish between blocks that are shared by zero or more caches (the conservative S state) and those that are not shared at all (I), instead of merging those into one single state as was done in the MSI protocol.

In this primer, we consider the E state to be an ownership state, which has a significant effect on the protocol. There are, however, protocols that do not consider the E state to be an ownership state, and the sidebar discusses the issues involved in such protocols.

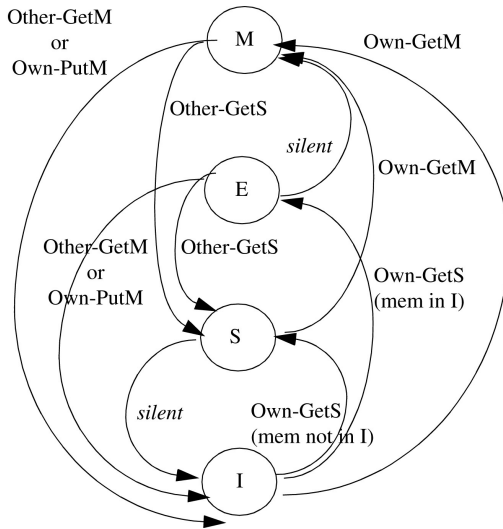

FIGURE 7.4: MESI: Transitions between stable states at cache controller

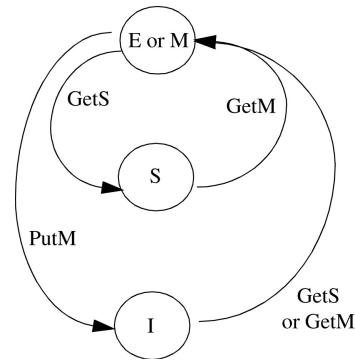

FIGURE 7.5: MESI: Transitions between stable states at memory controller

Sidebar: MESI Snooping if E is Non-ownership State

If the E state is not considered an ownership state (i.e., a block in E is owned by the LLC/memory), then the protocol must figure out which coherence controller should respond to a request after the memory controller has given a block to a cache in state E. Because the transition from state E to state M is silent, the memory controller cannot know whether the cache holds the block in E, in which case the LLC/memory is the owner, or in M, in which case the cache is the owner. If a GetS or GetM is serialized on the bus at this point, the cache can easily determine whether it is the owner and should respond, but the memory controller cannot make this same determination.

One solution to this problem is to have the LLC/memory wait for the cache to respond. When a GetS or GetM is serialized on the bus, a cache with the block in state M responds with data. The memory controller waits a fixed amount of time and, if no response appears in that window of time, the memory controller deduces that it is the owner and that it must respond. If a response from a cache does appear, the memory controller does not respond to the coherence request. This solution has a couple drawbacks, including potentially increased latency for responses from memory. Some implementations hide some or all of this latency by speculatively prefetching the block from memory, at the expense of increased memory bandwidth, power, and energy. A more significant drawback is having to design the system such that the caches' response latency is predictable and short.

7.3.4 Detailed Specification

In Tables 7.11 and 7.12, we present the detailed specification of the MESI protocol, including transient states. Differences with respect to the MSI protocol are highlighted with boldface font. The protocol adds to the set of cache states just the stable E state and the transient state EI^A, but there are several more LLC/memory states, including an extra transient state.

This MESI protocol shares all of the same simplifications present in the baseline MSI protocol. Coherence transactions are still atomic, etc.

TABLE 7.11: MESI Snooping Protocol—Cache Controller. A Shaded Entry Labeled “(A)” Denotes that this Transition is Impossible Because Transactions are Atomic on Bus.

7.3.5 Running Example

We now return to the running example, illustrated in Table 7.13. The execution differs from the MSI protocol almost immediately. When C1’s GetS appears on the bus, the LLC/memory is in state I and can thus send C1 Exclusive data. C1 observes the Exclusive data on the bus and changes its state to E (instead of S, as in the MSI protocol). The rest of the execution proceeds similarly to the MSI example, with minor transient state differences.

7.4 ADDING THE OWNED STATE

A second important optimization is the Owned state, and in this section, we describe how to create a MOSI snooping protocol by augmenting the baseline protocol from Section 7.2.3 with the O state. Recall from Chapter 2 that if a cache has a block in the Owned state, then the block is valid, read-only, dirty, and the cache is the owner, i.e., the cache must respond to coherence requests for the block. We maintain the same system model as the baseline snooping MSI protocol; transactions are atomic but requests are not atomic.

7.4.1 Motivation

Compared to an MSI or MESI protocol, adding the O state is advantageous in one specific and important situation: when a cache has a block in state M or E and receives a GetS from another core. In the MSI protocol of Section 7.2.3 and the MESI protocol of Section 7.3, the cache must change the block state from M or E to S and send the data to *both* the requestor *and* the memory controller.

TABLE 7.13: MESI: Example Execution

cycle	Core C1	Core C2	LLC/memory	request on bus	data on bus
1	issue GetS / IS ^{AD}				
2		issue GetM / IM ^{AD}			
3				GetS (C1)	
4	- / IS ^D		send exclusive data to C1 / EorM		
5					exclusive data from LLC/mem
6	copy data from LLC/mem / E			GetM (C2)	
7	send data to C2 / I	- / IM ^D	-/EorM		
8					data from C1
9		copy data from C1 / M			
10	issue GetS / IS ^{AD}				
11				GetS (C1)	
12	- / IS ^D	send data to C1 and to LLC/mem / S	- / S ^D		
13					data from C2
14	copy data from C2 / S		copy data from C2 / S		

The data must be sent to the memory controller because the responding cache relinquishes ownership (by downgrading to state S) and the LLC/memory becomes the owner and thus must thus have an up-to-date copy of the data with which to respond to subsequent requests.

Adding the O state achieves two benefits: (1) it eliminates the extra data message to update the LLC/memory when a cache receives a GetS request in the M (and E) state, and (2) it eliminates the potentially unnecessary write to the LLC (if the block is written again before being written back to the LLC). Historically, for multi-chip multiprocessors, there was a third benefit, which was that the O state allows subsequent requests to be satisfied by the cache instead of by the far-slower memory. Today, in a multicore with an inclusive LLC, as in the system model in this primer, the access latency of the LLC is not nearly as long as that of off-chip DRAM memory. Thus, having a cache respond instead of the LLC is not as big of a benefit as having a cache respond instead of memory.

We now present a MOSI protocol and show how it achieves these two benefits.

7.4.2 High-Level Protocol Specification

We specify a high-level view of the transitions between stable states in Figures 7.6 and 7.7. The key difference is what happens when a cache with a block in state M receives a GetS from another core. In a MOSI protocol, the cache changes the block state to O (instead of S) and retains ownership of the block (instead of transferring ownership to the LLC/memory). Thus, the O state enables the cache to avoid updating the LLC/memory.

7.4.3 Detailed Protocol Specification

In Tables 7.14 and 7.15, we present the detailed specification of the MOSI protocol, including transient states. Differences with respect to the MSI protocol are highlighted with boldface font. The protocol adds two transient cache states in addition to the stable O state. The transient OI^A state helps handle replacements of blocks in state O and the transient OM^A state handles upgrades back to state M after a store. The memory controller has no additional transient states, but we rename what had been the M state to MorO because the memory controller does not need to distinguish between these two states.

To keep the specification as concise as possible, we consolidate the PutM and PutO transactions into a single PutM transaction. That is, a cache evicts a block in state O with a PutM. This

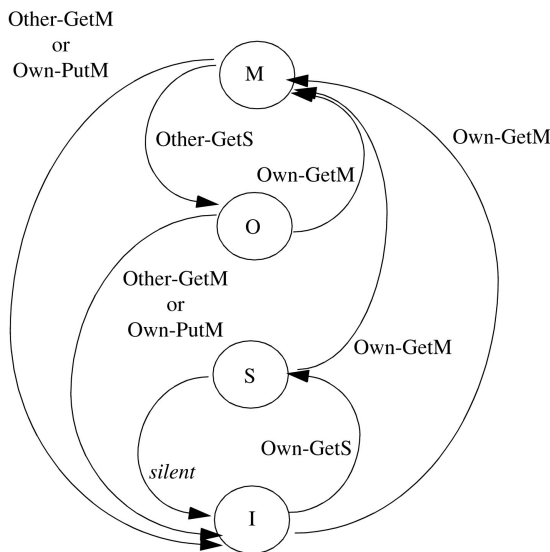

FIGURE 7.6: MOSI: Transitions between stable states at cache controller

SM ^{AD}	hit	stall	stall		-/SM ^D		-	-/IM ^{AD}	-	
SM ^D	hit	stall	stall				(A)	(A)	(A)	-/M
O	hit	issue GetM /OM ^A	issue PutM/OI ^A				send data to requestor	send data to requestor/I	-	
OM ^A	hit	stall	stall		-/M		send data to requestor	send data to requestor /IM ^{AD}	-	
M	hit	hit	issue PutM/MI ^A				send data to requestor/O	send data to requestor/I	-	
MI ^A	hit	hit	stall			send data to memory/I	send data to requestor /OI ^A	send data to requestor/II ^A	-	
OI ^A	hit	stall	stall			send data to memory /I	send data to requestor	send data to requestor/II ^A	-	
II ^A	stall	stall	stall			send NoData to memory/I	-	-	-	

decision has no impact on the protocol’s functionality, but does help to keep the tabular specification readable.

This MOSI protocol shares all of the same simplifications present in the baseline MSI protocol. Coherence transactions are still atomic, etc.

7.4.4 Running Example

In Table 7.16, we return to the running example that we introduced for the MSI protocol. The example proceeds identically to the MSI example until C1’s second GetS appears on the bus. In the MOSI protocol, this second GetS causes C2 to respond to C1 and change its state to O (instead

TABLE 7.15: MOSI Snooping Protocol—Memory Controller. A Shaded Entry Labeled “(A)” Denotes that this Transition is Impossible Because Transactions are Atomic on Bus.

MorO	-	-	-/MorO ^D		
MorO ^D	(A)	(A)		write data to mem- ory/IorS	-/MorO

of S). C2 retains ownership of the block and does not need to copy the data back to the LLC/memory (unless and until it evicts the block, not shown).

7.5 NON-ATOMIC BUS

The baseline MSI protocol, as well as the MESI and MOSI variants, all rely on the *Atomic Transactions* assumption. This atomicity greatly simplifies the design of the protocol, but it sacrifices performance.

TABLE 7.16: MOSI: Example Execution.

cycle	Core C1 (C1)	Core C2 (C2)	LLC/memory	request on bus	data on bus

7.5.1 Motivation

The simplest way to implement atomic transactions is to use a shared-wire bus with an atomic bus protocol; that is, all bus transactions consist of an indivisible request-response pair. Having an atomic bus is analogous to having an unpipelined processor core; there is no way to overlap activities that could proceed in parallel. Figure 7.8 illustrates the operation of an atomic bus. Because a coherence transaction occupies the bus until the response completes, an atomic bus trivially implements atomic transactions. However, the throughput of the bus is limited by the sum of the latencies for a request and response (including any wait cycles between request and response, not shown). Considering that a response could be provided by off-chip memory, this latency bottlenecks bus performance.

Figure 7.9 illustrates the operation of a pipelined, non-atomic bus. The key advantage is not having to wait for a response before a subsequent request can be serialized on the bus, and thus the bus can achieve much higher bandwidth using the same set of shared wires. However, implementing atomic transactions becomes much more difficult (but not impossible). The atomic transactions property restricts concurrent transactions to the same block, but not different blocks. The SGI Challenge enforced atomic transactions on a pipelined bus using a fast table lookup to check whether or not another transaction was already pending for the same block.

7.5.2 In-Order vs. Out-of-order Responses

One major design issue for a non-atomic bus is whether it is pipelined or split-transaction. A *pipelined* bus, as illustrated in Figure 7.9, provides responses in the same order as the requests. A *split-transaction* bus, illustrated in Figure 7.10, can provide responses in an order different from the request order.

The advantage of a split-transaction bus, with respect to a pipelined bus, is that a low-latency response does not have to wait for a long-latency response to a prior request. For example, if Request 1 is for a block owned by memory and not present in the LLC and Request 2 is for a block owned by an on-chip cache, then forcing Response 2 to wait for Response 1, as a pipelined bus would require, incurs a performance penalty.

One issue raised by a split-transaction bus is matching responses with requests. With an atomic bus, it is obvious that a response corresponds to the most recent request. With a pipelined bus, the requestor must keep track of the number of outstanding requests to determine which message is the response to its request. With a split-transaction bus, the response must carry the identity of the request or the requestor.

7.5.3 Non-Atomic System Model

We assume a system like the one illustrated in Figure 7.11. The request bus and the response bus are split and operate independently. Each coherence controller has connections to and from both

FIGURE 7.8: Atomic bus

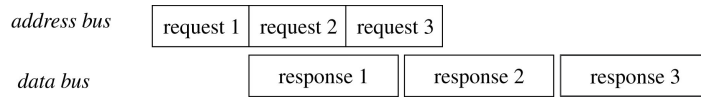

FIGURE 7.9: Pipelined (non-atomic) bus

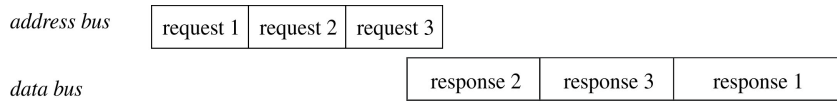

FIGURE 7.10: Split transaction (non-atomic) bus

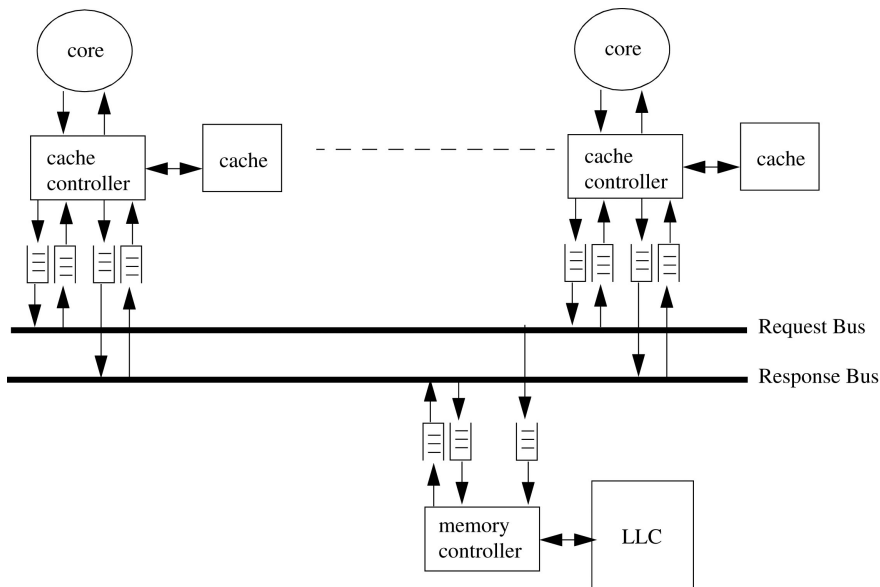

FIGURE 7.11: System model with split-transaction bus

buses, with the exception that the memory controller does not have a connection to make requests. We draw the FIFO queues for buffering incoming and outgoing messages because it is important to consider them in the coherence protocol. Notably, if a coherence controller stalls when processing an incoming request from the request bus, then all requests behind it (serialized after the stalled request) will not be processed by that coherence controller until it processes the currently stalled request. These queues are processed in a strict FIFO fashion, regardless of message type or address.

7.5.4 An MSI Protocol with a Split-Transaction Bus

In this section, we modify the baseline MSI protocol for use in a system with a split-transaction bus. Having a split-transaction bus does not change the transitions between stable states, but it has a large impact on the detailed implementation. In particular, there are many more possible transitions.

In Tables 7.17 and 7.18, we specify the protocol. Several transitions are now possible that were not possible with the atomic bus. For example, a cache can now receive an Other-GetS for a block it has in state IS^D . All of these newly possible transitions are for blocks in transient states in which the cache is awaiting a data response; while waiting for the data, the cache first observes another coherence request for the block. Recall from Section 7.1 that a transaction is ordered based on when its request is ordered on the bus, not when the data arrives at the requestor. Thus, in each of these newly possible transitions, the cache has already effectively completed its transaction but just happens to not have the data yet. Returning to our example of IS^D , the cache block is effectively in S. Thus, the arrival of an Other-GetS in this state requires no action to be taken because a cache with a block in S need not respond to an Other-GetS.

The newly possible transitions other than the above example, however, are more complicated. Consider a block in a cache in state IM^D when an Other-GetS is observed on the bus. The cache block is effectively in state M and the cache is thus the owner of the block but does not yet have the block's data. Because the cache is the owner, the cache must respond to the Other-GetS, yet the cache cannot respond until it receives the data. The simplest solution to this situation is for the cache to stall processing of the Other-GetS until the data response arrives for its Own-GetM. At that point, the cache block will change to state M and the cache will have valid data to send to the requestor of the Other-GetS.

For the other newly possible transitions, at both the cache controller and the memory controller, we also choose to stall until data arrives to satisfy the in-flight request. This is the simplest approach, but it raises three issues. First, it sacrifices some performance, as we discuss in the next section.

TABLE 7.17: MSI Snooping Protocol with Split-Transaction Bus—Cache Controller

	load	store	replacement	OwnGetS or OwnGetM	OwnGetM	OwnPutM	OtherGetS	OtherGetM	OtherPutM	Own Data response (for own request)
I	issue GetS/IS ^{AD}	issue GetM/IM ^{AD}					-	-	-	
IS ^{AD}	stall	stall	stall	-/IS ^D			-	-	-	-/IS ^A
IS ^D	stall	stall	stall				-	stall		load hit/S
IS ^A	stall	stall	stall	load hit/S			-	-		
IM ^{AD}	stall	stall	stall		-/IM ^D		-	-	-	-/IM ^A
IM ^D	stall	stall	stall				stall	stall		store hit/M
IM ^A	stall	stall	stall		store hit/M		-	-		
S	hit	issue GetM/SM ^{AD}	-/I				-	-/I		
SM ^{AD}	hit	stall	stall		-/SM ^D		-	-/IM ^{AD}		-/SM ^A
SM ^D	hit	stall	stall				stall	stall		store hit/M
SM ^A	hit	stall	stall		store hit/M		-	-/IM ^A		
M	hit	hit	issue PutM/MI ^A				send data to requestor and to memory/S	send data to requestor/I		
MI ^A	hit	hit	stall			send data to requestor /I	send data to requestor and to memory/II ^A	send data to requestor/II ^A		
II ^A	stall	stall	stall			-/I	-	-	-	

Second, stalling raises the potential of deadlock. If a controller can stall on a message while awaiting another event (message arrival), the architect must ensure that the awaited event will eventually occur. Circular chains of stalls can lead to deadlock and must be avoided. In our protocol in this section, controllers that stall are guaranteed to receive the messages that un-stall them. This guarantee is easy to see because the controller has already seen its own request, the stall only affects the request network, and the controller is waiting for a Data message on the response network.

TABLE 7.18: MSI Snooping Protocol with Split-Transaction Bus—Memory Controller

	GetS	GetM	PutM from Owner	PutM from Non-Owner	Data
IorS	send data to requestor	send data to requestor, set Owner to requestor/M		-	
M	clear Owner/IorS ^D	set Owner to requestor	clear Owner/IorS ^D	-	write data to memory/IorS ^A
IorS ^D	stall	stall	stall	-	write data to memory/IorS
IorS ^A	clear Owner/IorS	-	clear Owner/IorS	-	

The third issue raised by stalling coherence requests is that, perhaps surprisingly, it enables a requestor to observe a response to its request before processing its own request. Consider the example in Table 7.19. Core C1 issues a GetM for block X and changes the state of X to IM^{AD}. C1 observes its GetM on the bus and changes state to IM^D. The LLC/memory is the owner of X and takes a long time to retrieve the data from memory and put it on the bus. In the meanwhile, core C2 issues a GetM for X that gets serialized on the bus but cannot be processed by C1 (i.e., C1 stalls). C1 issues a GetM for block Y that then gets serialized on the bus. This GetM for Y is queued up behind the previously stalled coherence request at C1 (the GetM from C2) and thus C1 cannot process its own GetM for Y. However, the owner, C2, can process this GetM for Y and responds quickly to C1. Thus, C1 can observe the response to its GetM for Y before processing its request. This possibility requires the addition of transient states. In this example, core C1 changes the state of block Y from IM^{AD} to IM^A. Similarly, the protocol also needs to add transient states IS^A and SM^A. In these transient states, in which the response is observed before the request, the block is effectively in the prior state. For example, a block in IM^A is logically in state I because the GetM has not been processed yet; the cache controller does not respond to an observed GetS or GetM if the block is in IM^A. We contrast IM^A with IM^D—in IM^D, the block is logically in M and the cache controller must respond to observed GetS or GetM requests once data arrives.

This protocol has one other difference with respect to the previous protocols in this chapter, and the difference pertains to PutM transactions. The situation that is handled differently is when a core, say, core C1, issues a PutM, and a GetS or GetM from another core for the same block gets ordered before C1's PutM. C1 transitions from state MI^A to II^A before it observes its own PutM. In the atomic protocols earlier in this chapter, C1 observes its own PutM and sends a NoData message to the LLC/memory. The NoData message informs the LLC/memory that the PutM transaction is complete (i.e., it does not have to wait for data). C1 cannot send a Data message to the LLC/memory in this situation because C1's data are stale and the protocol cannot send the LLC/memory stale data that would then overwrite the up-to-date value of the data. In the non-atomic protocols

TABLE 7.19: Example: Response Before Request. Initially, Block X is in State I in Both Caches and Block Y is in State M at Core C2.

cycle	Core C1	Core C2	LLC/memory	request on bus	data on bus
initial	X:I Y:I	X:I Y:M	X:I Y:M		
1	X: store miss; issue GetM/ IM ^{AD}				
2				X: GetM (C1)	
3	X: process GetM (C1) / IM ^D	X: process GetM (C1) - ignore;	X: process GetM (C1) - LLC miss, start accessing X from DRAM		
4		X:store miss; issue GetM/ IM ^{AD}			
5	Y: store miss; issue GetM/ IM ^{AD}			X: GetM (C2)	
6	X: stall on GetM (C2)	X: process GetM (C2) / IM ^D	X: process GetM (C2) - ignore	Y: GetM (C1)	
7	Y: process GetM/ IM ^D	Y: process GetM (C1) - send data to C1 / I	Y: process GetM (C1) - ignore		
8					Y: data from C2
9	Y: write data into cache /IM^A				
10			X: LLC miss completes, send data to C1		
11					X: data from LLC
12	X: write data into cache/ M Perform store				
13	X: (unstall) process GetM (C2) - send data to C2 / I				
14	Y: process (in-order) GetM (C1) / M ; perform store				X: data from C1
15		X: write data into cache/M perform store			

in this chapter, we augment the state of each block in the LLC with a field that holds the identity of the current owner of the block. The LLC updates the owner field of a block on every transaction that changes the block's ownership. Using the owner field, the LLC can identify situations in which a PutM from a non-owner is ordered on the bus; this is exactly the same situation in which C1 is in state II^A when it observes its PutM. Thus, the LLC knows what happened and C1 does not have to send a NoData message to the LLC. We chose to modify how PutM transactions are handled in the non-atomic protocols, compared to the atomic protocols, for simplicity. Allowing the LLC to directly identify this situation is simpler than requiring the use of NoData messages; with a non-atomic protocol, there can be a large number of NoData messages in the system and NoData messages can arrive before their associated PutM requests.

7.5.5 An Optimized, Non-Stalling MSI Protocol with a Split-Transaction Bus

As mentioned in the previous section, we sacrificed some performance by stalling on the newly possible transitions of the system with the split-transaction bus. For example, a cache with a block in state IS^D stalled instead of processing an Other-GetM for that block. However, it is possible that there are one or more requests after the Other-GetM, to other blocks, that the cache could process without stalling. By stalling a request, the protocol stalls all requests after the stalled request and delays those transactions from completing. Ideally, we would like a coherence controller to process requests behind a request that is stalled, but recall that—to support a total order of memory requests—snooping requires coherence controllers to observe and process requests in the order received. Reordering is not allowed.

The solution to this problem is to process all messages, in order, instead of stalling. Our approach is to add transient states that reflect messages that the coherence controller has received but must remember to complete at a later event. Returning to the example of a cache block in IS^D , if the cache controller observes an Other-GetM on the bus, then it changes the block state to IS^{DI} (which denotes “in I, going to S, waiting for data, and when data arrives will go to I”). Similarly, a block in IM^D that receives an Other-GetS changes state to IM^{DS} and must remember the requestor of the Other-GetS. When the data arrive in response to the cache’s GetM, the cache controller sends the data to the requestor of the Other-GetS and changes the block’s state to S.

In addition to the proliferation of transient states, a non-stalling protocol introduces a potential livelock problem. Consider a cache with a block in IM^{DS} that receives the data in response to its GetM. If the cache *immediately* changes the block state to S and sends the data to the requestor of the Other-GetS, it does not get to perform the store for which it originally issued its GetM. If the core then re-issues the GetM, the same situation could arise again and again, and the store might never perform. To guarantee that this livelock cannot arise, we require that a cache in IS^{DI} , IM^{DI} , IM^{DS} , or IM^{DSI} (or any comparable state in a protocol with additional stable coherence states) perform one load or store to the block when it receives the data for its request.⁶ After performing one load or store, it may then change state and forward the block to another cache. We defer a more in-depth treatment of livelock to Section 9.3.2.

We present the detailed specification of the non-stalling MSI protocol in Tables 7.20 and 7.21. The most obvious difference is the number of transient states. There is nothing inherently complicated about any of these states, but they do add to the overall complexity of the protocol.

We have not removed the stalls from the memory controller because it is not feasible. Consider a block in $IorS^D$. The memory controller observes a GetM from core C1 and currently stalls.

⁶The load or store must be performed *if and only if* that load or store was the oldest load or store in program order when the coherence request was first issued. We discuss this issue in more detail in Section 9.3.2.

TABLE 7.20: Optimized MSI Snooping with Split-Transaction Bus—Cache Controller

	load	store	replacement	OwnGetS	OwnGetM	OwnPutM	OtherGetS	OtherGetM	OtherPutM	Own Data response

MI ^A	hit	hit	stall			send data to requestor/I	send data to requestor and to memory/II ^A	send data to requestor/II ^A		
II ^A	stall	stall	stall			-/I	-	-	-	

TABLE 7.21: Optimized MSI Snooping with Split-Transaction Bus—Memory Controller

	GetS	GetM	PutM from Owner	PutM from Non-Owner	Data
IorS	send data to requestor	send data to requestor, set owner to requestor/M		-	
M	clear Owner/IorS ^D	set Owner to requestor	clear Owner/IorS ^D	-	write data to memory/IorS ^A
IorS ^D	stall	stall	stall	-	write data to memory/IorS
IorS ^A	clear Owner/IorS	-	clear Owner/IorS	-	

However, it would appear that we could simply change the block's state to IorS^{DM} while waiting for the data. Yet, while in IorS^{DM}, the memory controller could observe a GetS from core C2. If the memory controller does not stall on this GetS, it must change the block state to IorS^{DMIorS^D}. In this state, the memory controller could observe a GetM from core C3. There is no elegant way to bound the number of transient states needed at the LLC/memory to a small number (i.e., smaller than the number of cores) and so, for simplicity, we have the memory controller stall.

7.6 OPTIMIZATIONS TO THE BUS INTERCONNECTION NETWORK

So far in this chapter we have assumed system models in which there exists a single shared-wire bus for coherence requests and responses or dedicated shared-wire buses for requests and responses. In this section, we explore two other possible system models that enable improved performance.

7.6.1 Separate Non-Bus Network for Data Responses

We have emphasized the need of snooping systems to provide a total order of broadcast coherence requests. The example in Table 7.2 showed how the lack of a total order of coherence requests can lead to incoherence. However, there is no such need to order coherence *responses*, nor is there a need to broadcast them. Thus, coherence responses could travel on a separate network that does not support broadcast or ordering. Such networks include crossbars, meshes, tori, butterflies, etc.

There are several advantages to using a separate, non-bus network for coherence responses.

- **Implementability:** it is difficult to implement high-speed shared-wire buses, particularly for systems with many controllers on the bus. Other topologies can use point-to-point links.
- **Throughput:** a bus can provide only one response at a time. Other topologies can have multiple responses in-flight at a time.
- **Latency:** using a bus for coherence responses requires that each response incur the latency to arbitrate for the bus. Other topologies can allow responses to be sent immediately without arbitration.

7.6.2 Logical Bus for Coherence Requests

Snooping systems require that there exist a total order of broadcast coherence requests. A shared-wire bus for coherence requests is the most straightforward way to achieve this total order of broadcasts, but it is not the only way to do so. There are two ways to achieve the same totally ordered broadcast properties as a bus (i.e., a logical bus) without having a physical bus.

- Other topologies with physical total order: a shared-wire bus is the most obvious topology for achieving a total order of broadcasts, but other topologies exist. One notable example is a tree with the coherence controllers at the leaves of the tree. If all coherence requests are unicasted to the root of the tree and then broadcast down the tree, then each coherence controller observes the same total order of coherence broadcasts. The serialization point in this topology is the root of the tree. Sun Microsystems used a tree topology in its Starfire multiprocessor [3], which we discuss in detail in Section 7.7.
- Logical total order: a total order of broadcasts can be obtained even without a network topology that naturally provides such an order. The key is to order the requests in logical time. Martin et al. [6] designed a snooping protocol, called Timestamp Snooping, that can function on any network topology. To issue a coherence request, a cache controller broadcasts it to every coherence controller and labels the broadcast with the logical time at which the broadcast message should be ordered. The protocol must ensure that (a) every broadcast has a distinct logical time, (b) coherence controllers process requests in logical time order (even when they arrive out of this order in physical time), and (c) no request at logical time T can arrive at a controller after that controller has passed logical time T . Agarwal et al. recently proposed a similar scheme called In-Network Snoop Ordering (INSO) [1].

Flashback to Quiz Question 7: A snooping cache coherence protocol requires the cores to communicate on a bus. *True or false?*

Answer: *False!* Snooping requires a totally ordered broadcast network, but that functionality can be implemented without a physical bus.

7.7 CASE STUDIES

We present two examples of real-world snooping systems: the Sun Starfire E10000 and the IBM Power5.

7.7.1 Sun Starfire E10000

Sun Microsystems's Starfire E10000 [3] is an interesting example of a commercial system with a snooping protocol. The coherence protocol itself is not that remarkable; the protocol is a typical

MOESI snooping protocol with write-back caches. What distinguishes the E10000 is how it was designed to scale up to 64 processors. The architects innovated based on three important observations, which we discuss in turn.

First, shared-wire snooping buses do not scale to large numbers of cores, largely due to electrical engineering constraints. In response to this observation, the E10000 uses only point-to-point links instead of buses. Instead of broadcasting coherence requests on physical (shared-wire) buses, the E10000 broadcasts coherence requests on a *logical* bus. The key insight behind snooping protocols is that they require a total order of coherence requests, but this total order does not require a physical bus. As illustrated in Figure 7.12, the E10000 implements a logical bus as a tree, in which the processors are the leaves. All links in the tree are point-to-point, thus eliminating the need for buses. A processor unicasts a request up to the top of the tree, where it is serialized and then broadcast down the tree. Because of the serialization at the root, the tree provides totally ordered broadcast. A given request may arrive at two processors at different times, which is fine; the important constraint is that the processors observe the same total order of requests.

The second observation made by the E10000 architects is that greater coherence request bandwidth can be achieved by using multiple (logical) buses, while still maintaining a total order of coherence requests. The E10000 has four logical buses, and coherence requests are address-interleaved across them. A total order is enforced by requiring processors to snoop the logical buses in a fixed, pre-determined order.

Third, the architects observed that data response messages, which are much larger than request messages, do not require the totally ordered broadcast network required for coherence requests.

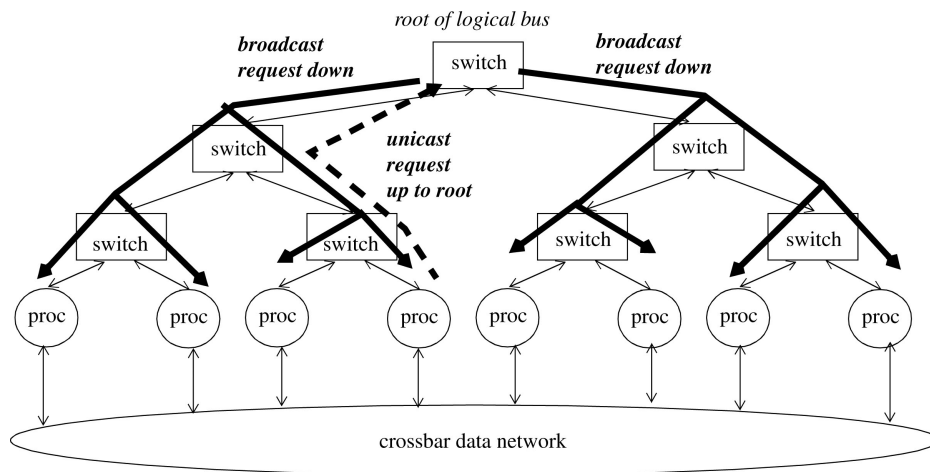

FIGURE 7.12: Starfire E10000 (drawn with only eight processors for clarity). A coherence request is unicast up to the root, where it is serialized, before being broadcast down to all processors.

Many prior snooping systems implemented a data bus, which needlessly provides both broadcasting and total ordering, while limiting bandwidth. To improve bandwidth, the E10000 implements the data network as a crossbar. Once again, there are point-to-point links instead of buses, and the bandwidth of the crossbar far exceeds what would be possible with a bus (physical or logical).

The architecture of the E10000 has been optimized for scalability, and this optimized design requires the architects to reason about non-atomic requests and non-atomic transactions.

7.7.2 IBM Power5

The IBM Power5 [8] is a 2-core chip in which both cores share an L2 cache. Each Power5 chip has a fabric bus controller (FBC) that enables multiple Power5 chips to be connected together to create larger systems. Large systems contain up to eight nodes, where each node is a multi-chip module (MCM) with four Power5 chips.

Viewed abstractly, the IBM Power5 appears to use a fairly typical MESI snooping protocol implemented atop a split-transaction bus. However, this simplistic description misses several unique features that are worth discussing. In particular, we focus on two aspects: the ring topology of the interconnection network and the addition of novel variants of the MESI coherence states.

7.7.2.1 Snooping Coherence on a Ring

The Power5 uses an interconnection network that is quite different from what we have discussed thus far, and these differences have important impacts on the coherence protocol. Most significantly, the Power5 connects nodes with three unidirectional rings, which are used for carrying three types of messages: requests, snoop responses/decision messages, and data. Unidirectional rings do not provide a total order, unless all messages are required to start from the same node on the ring, which the Power5 does not. Rather, the requestor sends a request message around the ring and then absorbs the request when it sees it arrive back after traveling the entire ring. Each node observes the request on the ring and every processor in the node determines its snoop response. The first node to observe the request provides a single snoop response that is the aggregated snoop response of all of the processors on that node. A snoop response is *not* an actual data response, but rather a description of the action the chip or node would take. Without a totally ordered network, the chips/nodes cannot immediately act because they might not make consistent decisions about how to respond. The snoop response travels on the snoop response ring to the next node. This node similarly produces a single snoop response that aggregates the snoop response of the first node plus the snoop responses of all processors on the second node. When the aggregated snoop response of all nodes reaches the requestor chip, the requestor chip determines what every processor should do to respond to the request. The requestor chip broadcasts this decision along the ring to every node. This decision

message is processed by every node/chip in the ring, and the node/chip that has been determined to be the one to provide a data response sends that data response on the data ring to the requestor.

This protocol is far more complicated than typical snooping protocols because of the lack of a totally ordered interconnection network. The protocol still has a total logical order of coherence requests, but without a totally ordered network, a node cannot immediately respond to a request because the request's position in the total order has not yet been determined by when it appears on the network. Despite the complexity, the Power5 design offers the advantages of having only point-to-point links and the simplicity of the ring topology (e.g., routing in a ring is so simple that switching can be faster than for other topologies). There have been other protocols that have exploited ring topologies and explored ordering issues for rings [2, 4, 7].

7.7.2.2 Extra Variants of Coherence States

The Power5 protocol is fundamentally a MESI protocol, but it has several “flavors” of some of these states. We list all of the states in Table 7.22. There are two new states that we wish to highlight. First, there is the SL variant of the Shared state. If an L2 cache holds a block in state SL, it may respond with data to a GetS from a processor on the same node, thus reducing this transaction's latency and reducing off-chip bandwidth demand; this ability to provide data distinguishes SL from S.

TABLE 7.22: Power5 L2 Cache Coherence States

State	Permissions	Description
I	none	Invalid
S	read-only	Shared
SL	read-only	Shared local data source, but can respond with data to requests from processors in same node (sometimes referred to as F state, as in Intel QuickPath protocol (Section 8.8.4))
S (S)	read-only	Shared
Me (E)	read-write	Exclusive
M (M)	read-write	Modified
Mu	read-write	Modified unsolicited - received read-write data in response to read-only request
T	read-only	Tagged - was M, received GetS. T is sometime described as being a read-write state, which violates the SWMR invariant since there are also blocks in state S. A better way to think of T is that it is like E: it can immediately transition to M. However, unlike E, this transition is not silent: a store to a block in T state immediately transitions to M but (atomically) issues an invalidation message on the ring. Although other caches may race with this request, the T state has priority, and thus is guaranteed to be ordered first and thus does not need to wait for the invalidations to complete.

The other interesting new state is the T(agged) state. A block enters the T state when it is in Modified and receives a GetS request. Instead of downgrading to S, which it would do in a MESI protocol, or O, which it would do in a MOSI protocol, the cache changes the state to T. A block in state T is similar to the O state, in that it has a value that is more recent than the value in memory, and there may or may not be copies of the block in state S in other caches. Like the O state, the block may be read in the T state. Surprisingly, the T state is sometimes described as being a read-write state, which violates the SWMR invariant. Indeed, a store to state T may be performed immediately, and thus indeed violates the SWMR invariant in real (physical) time. However, the protocol still enforces the SWMR invariant in a logical time based on ring-order. Although the details of this ordering are beyond the scope of this primer, we think it helps to think of the T state as a variation on the E state. Recall that the E state allows a silent transition to M; thus a store to a block in state E may be immediately performed, so long as the state (atomically) transitions to state M. The T state is similar; a store in state T immediately transitions to state M. However, because there may also be copies in state S, a store in state T also causes the immediate issue of an invalidation message on the ring. Other cores may be attempting to upgrade from I or S to M, but the T state acts as the coherence ordering point and thus has priority and need not wait for an acknowledgment. It is not clear that this protocol is sufficient to support strong memory consistency models such as SC and TSO; however, as we discussed in Chapter 5, the Power memory model is one of the weakest memory consistency models. This Tagged state optimizes the common scenario of producer-consumer sharing, in which one thread writes a block and one or more other threads then read that block. The producer can re-obtain read-write access without having to wait as long each time.

7.8 DISCUSSION AND THE FUTURE OF SNOOPING

Snooping systems were prevalent in early multiprocessors because of their reputed simplicity and because their lack of scalability did not matter for the relatively small systems that dominated the market. Snooping also offers performance advantages for non-scalable systems because every snooping transaction can be completed with two messages, which we will contrast against the three-message transactions of directory protocols.

Despite its advantages, snooping is no longer commonly used. Even for small-scale systems, where snooping's lack of scalability is not a concern, snooping is no longer common. Snooping's requirement of a totally ordered broadcast network is just too costly, compared to the low-cost interconnection networks that suffice for directory protocols. Furthermore, for scalable systems, snooping is clearly a poor fit. Systems with very large numbers of cores are likely to be bottlenecked by both the interconnection network bandwidth needed to broadcast requests and the coherence controller bandwidth required to snoop every request. For such systems, a more scalable coherence

protocol is required, and it is this need for scalability that originally motivated the directory protocols we present in the next chapter.

CHAPTER 8

Directory Coherence Protocols

In this chapter, we present directory coherence protocols. Directory protocols were originally developed to address the lack of scalability of snooping protocols. Traditional snooping systems broadcast all requests on a totally ordered interconnection network and all requests are snooped by all coherence controllers. By contrast, directory protocols use a level of indirection to avoid both the ordered broadcast network and having each cache controller process every request.

We first introduce directory protocols at a high level (Section 8.1). We then present a system with a complete but unsophisticated three-state (MSI) directory protocol (Section 8.2). This system and protocol serve as a baseline upon which we later add system features and protocol optimizations. We then explain how to add the Exclusive state (Section 8.3) and the Owned state (Section 8.4) to the baseline MSI protocol. Next we discuss how to represent the directory state (Section 8.5) and how to design and implement the directory itself (Section 8.6). We then describe techniques for improving performance and reducing the implementation costs (Section 8.7). We then discuss commercial systems with directory protocols (Section 8.8) before concluding the chapter with a discussion of directory protocols and their future (Section 8.9).

Those readers who are content to learn just the basics of directory coherence protocols can skim or skip Section 8.3 through Section 8.7, although some of the material in these sections will help the reader to better understand the case studies in Section 8.8.

8.1 INTRODUCTION TO DIRECTORY PROTOCOLS

The key innovation of directory protocols is to establish a *directory* that maintains a global view of the coherence state of each block. The directory tracks which caches hold each block and in what states. A cache controller that wants to issue a coherence request (e.g., a GetS) sends it directly to the directory (i.e., a unicast message), and the directory looks up the state of the block to determine what actions to take next. For example, the directory state might indicate that the requested block is owned by core C2's cache and thus the request should be forwarded to C2 (e.g., using a new Fwd-GetS request) to obtain a copy of the block. When C2's cache controller receives this forwarded request, it unicasts a response to the requesting cache controller.

It is instructive to compare the basic operation of directory protocols and snooping protocols. In a directory protocol, the directory maintains the state of each block, and cache controllers send all requests to the directory. The directory either responds to the request or forwards the request to one or more other coherence controllers that then respond. Coherence transactions typically involve either two steps (a unicast request, followed by a unicast response) or three steps (a unicast request, $K \geq 1$ forwarded requests, and K responses, where K is the number of sharers). Some protocols even have a fourth step, either because responses indirect through the directory or because the requestor notifies the directory on transaction completion. In contrast, snooping protocols distribute a block's state across potentially all of the coherence controllers. Because there is no central summary of this distributed state, coherence requests must be broadcast to all coherence controllers. Snooping coherence transactions thus always involve two steps (a broadcast request, followed by a unicast response).

Like snooping protocols, a directory protocol needs to define when and how coherence transactions become ordered with respect to other transactions. In most directory protocols, a coherence transaction is ordered at the directory. Multiple coherence controllers may send coherence requests to the directory at the same time, and the transaction order is determined by the order in which the requests are serialized at the directory. If two requests race to the directory, the interconnection network effectively chooses which request the directory will process first. The fate of the request that arrives second is a function of the directory protocol and what types of requests are racing. The second request might get (a) processed immediately after the first request, (b) held at the directory while awaiting the first request to complete, or (c) negatively acknowledged (NACKed). In the latter case, the directory sends a negative acknowledgment message (NACK) to the requestor, and the requestor must re-issue its request. In this chapter, we do not consider protocols that use NACKs, but we do discuss the possible use of NACKs and how they can cause livelock problems in Section 9.3.2.

Using the directory as the ordering point represents another key difference between directory protocols and snooping protocols. Traditional snooping protocols create a total order by serializing all transactions on the ordered broadcast network. Snooping's total order not only ensures that each block's requests are processed in per-block order but also facilitates implementing a memory consistency model. Recall that traditional snooping protocols use totally ordered broadcast to serialize all requests; thus, when a requestor observes its own coherence request this serves as notification that its coherence epoch may begin. In particular, when a snooping controller sees its own GetM request, it can infer that other caches will invalidate their S blocks. We demonstrated in Table 7.4 that this serialization notification is sufficient to support the strong SC and TSO memory consistency models.

In contrast, a directory protocol orders transactions at the directory to ensure that conflicting requests are processed by all nodes in per-block order. However, the lack of a total order means that a requestor in a directory protocol needs another strategy to determine when its request has been serialized and thus when its coherence epoch may safely begin. Because (most) directory protocols do not use totally ordered broadcast, there is no global notion of serialization. Rather, a request must be individually serialized with respect to all the caches that (may) have a copy of the block. Explicit messages are needed to notify the requestor that its request has been serialized by each relevant cache. In particular, on a GetM request, each cache controller with a shared (S) copy must send an explicit acknowledgment (Ack) message once it has serialized the invalidation message.

This comparison between directory and snooping protocols highlights the fundamental trade-off between them. A directory protocol achieves greater scalability (i.e., because it requires less bandwidth) at the cost of a level of indirection (i.e., having three steps, instead of two steps, for some transactions). This additional level of indirection increases the latency of some coherence transactions.

8.2 BASELINE DIRECTORY SYSTEM

In this section, we present a baseline system with a straightforward, modestly optimized directory protocol. This system provides insight into the key features of directory protocols while revealing inefficiencies that motivate the features and optimizations presented in subsequent sections of this chapter.

8.2.1 Directory System Model

We illustrate our directory system model in Figure 8.1. Unlike for snooping protocols, the topology of the interconnection network is intentionally vague. It could be a mesh, torus, or any other topology that the architect wishes to use. One restriction on the interconnection network that we assume in this chapter is that it enforces point-to-point ordering. That is, if controller A sends two messages to controller B, then the messages arrive at controller B in the same order in which they were sent.¹ Having point-to-point ordering reduces the complexity of the protocol, and we defer a discussion of networks without ordering until Section 8.7.3.

The only differences between this directory system model and the baseline system model in Figure 2.1 is that we have added a directory and we have renamed the memory controller to be the

¹Strictly speaking, we require point-to-point order for only certain types of messages, but this is a detail that we defer until Section 8.7.3.

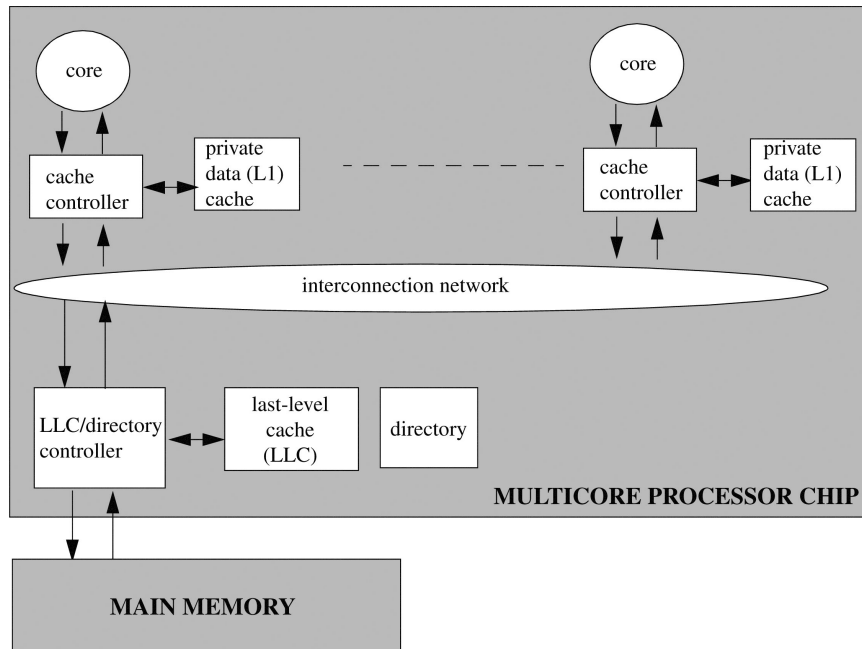

FIGURE 8.1: Directory system model.

directory controller. There are many ways of sizing and organizing the directory, and for now we assume the simplest model: for each block in memory, there is a corresponding directory entry. In Section 8.6, we examine and compare more practical directory organization options. We also assume a monolithic LLC with a single directory controller; in Section 8.7.1, we explain how to distribute this functionality across multiple banks of an LLC and multiple directory controllers.

8.2.2 High-Level Protocol Specification

The baseline directory protocol has only three stable states: MSI. A block is owned by the directory controller unless the block is in a cache in state M. The directory state for each block includes the stable coherence state, the identity of the owner (if the block is in state M), and the identities of the

FIGURE 8.2: Directory entry for a block in a system with N nodes.

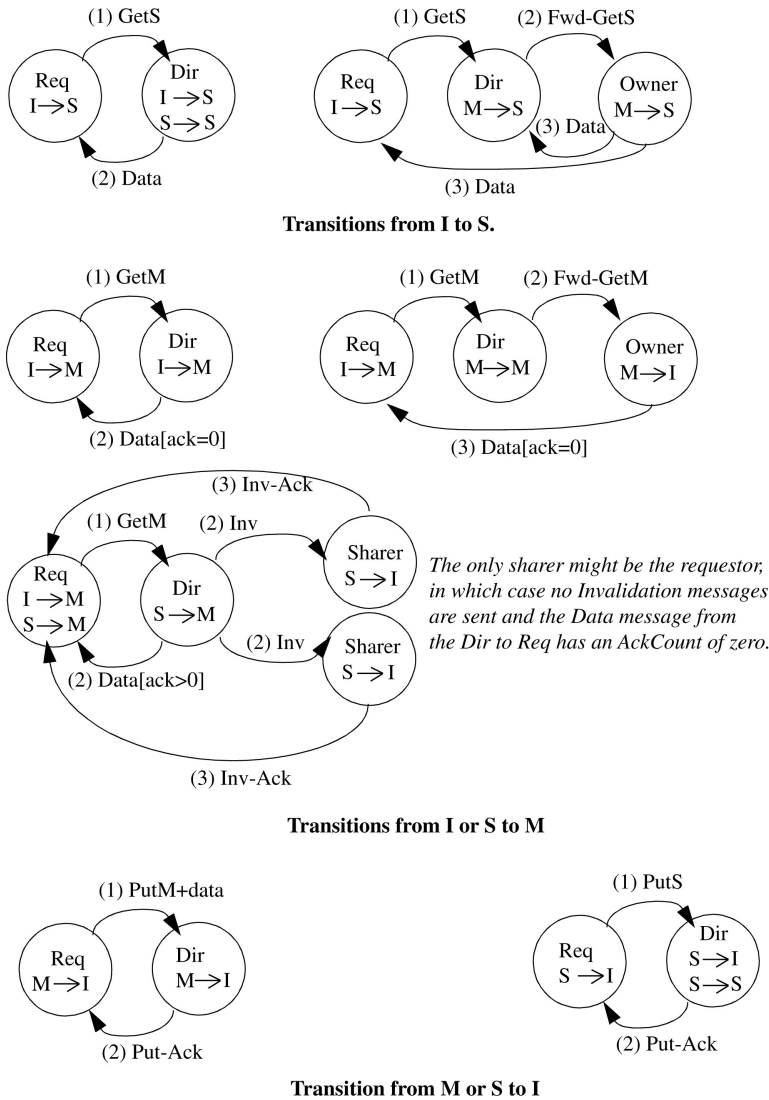

FIGURE 8.3: High-Level Description of MSI Directory Protocol. In each transition, the cache controller that requests the transaction is denoted “Req”.

sharers encoded as a one-hot bit vector (if the block is in state S). We illustrate a directory entry in Figure 8.2. In Section 8.5, we will discuss other encodings of directory entries.

Before presenting the detailed specification, we first illustrate a higher level abstraction of the protocol in order to understand its fundamental behaviors. In Figure 8.3, we show the transactions in which a cache controller issues coherence requests to change permissions from I to S, I or S to

M, M to I, and S to I. As with the snooping protocols in the last chapter, we specify the directory state of a block using a cache-centric notation (e.g., a directory state of M denotes that there exists a cache with the block in state M). Note that a cache controller may not silently evict a Shared block; that is, there is an explicit PutS request. We defer a discussion of protocols with silent evictions of shared blocks, as well as a comparison of silent versus explicit PutS requests, until Section 8.7.4.

Most of the transactions are fairly straightforward, but two transactions merit further discussion here. The first is the transaction that occurs when a cache is trying to upgrade permissions from I or S to M and the directory state is S. The cache controller sends a GetM to the directory, and the directory takes two actions. First, it responds to the requestor with a message that includes the data and the “AckCount”; the AckCount is the number of current sharers of the block. The directory sends the AckCount to the requestor to inform the requestor of how many sharers must acknowledge having invalidated their block in response to the GetM. Second, the directory sends an Invalidation (Inv) message to all of the current sharers. Each sharer, upon receiving the Invalidation, sends an Invalidation-Ack (Inv-Ack) to the requestor. Once the requestor receives the message from the directory and *all* of the Inv-Ack messages, it completes the transaction. The requestor, having received all of the Inv-Ack messages, knows that there are no longer any readers of the block and thus it may write to the block without violating coherence.

The second transaction that merits further discussion occurs when a cache is trying to evict a block in state M. In this protocol, we have the cache controller send a PutM message that includes the data to the directory. The directory responds with a Put-Ack. If the PutM did not carry the data with it, then the protocol would require a third message—a data message from the cache controller to the directory with the evicted block that had been in state M—to be sent in a PutM transaction. The PutM transaction in this directory protocol differs from what occurred in the snooping protocol, in which a PutM did not carry data.

8.2.3 Avoiding Deadlock

In this protocol, the reception of a message can cause a coherence controller to send another message. In general, if event A (e.g., message reception) can cause event B (e.g., message sending) and both these events require resource allocation (e.g., network links and buffers), then we must be careful to avoid deadlock that could occur if circular resource dependences arise. For example, a GetS request can cause the directory controller to issue a Fwd-GetS message; if these messages use the same resources (e.g., network links and buffers), then the system can potentially deadlock. In Figure 8.4, we illustrate a deadlock in which two coherence controllers C1 and C2 are responding to each other’s requests, but the incoming queues are already full of other coherence requests. If the queues are FIFO, then the responses cannot pass the requests. Because the queues are full, each con-

FIGURE 8.4: Deadlock example.

troller stalls trying to send a response. Because the queues are FIFO, the controller cannot switch to work on a subsequent request (or get to the response). Thus, the system deadlocks.

A well-known solution for avoiding deadlock in coherence protocols is to use separate networks for each class of message. The networks can be physically separate or logically separate (called *virtual networks*), but the key is avoiding dependences between classes of messages. Figure 8.5 illustrates a system in which request and response messages travel on separate physical networks. Because a response cannot be blocked by another request, it will eventually be consumed by its destination node, breaking the cyclic dependence.

The directory protocol in this section uses three networks to avoid deadlock. Because a request can cause a forwarded request and a forwarded request can cause a response, there are three message classes that each require their own network. Request messages are GetS, GetM, and PutM. Forwarded request messages are Fwd-GetS, Fwd-GetM, Inv(alidation), and Put-Ack. Response messages are Data and Inv-Ack. The protocols in this chapter require that the Forwarded Request network provides point-to-point ordering; other networks have no ordering constraints nor are there any ordering constraints between messages traveling on different networks.

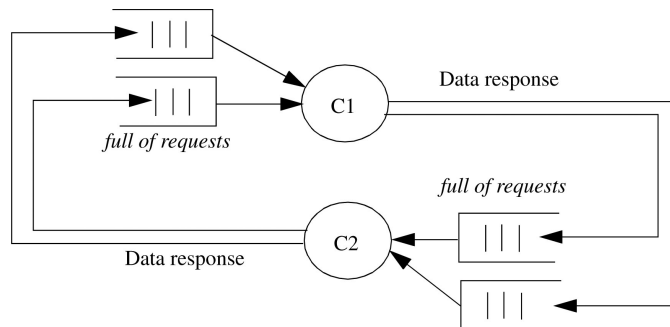

FIGURE 8.5: Avoiding deadlock with separate networks.

We defer a more thorough discussion of deadlock avoidance, including more explanation of virtual networks and the exact requirements for avoiding deadlock, until Section 9.3.

8.2.4 Detailed Protocol Specification

We present the detailed protocol specification, including all transient states, in Tables 8.1 and 8.2. Compared to the high-level description in Section 8.2.2, the most significant difference is the transient states. The coherence controllers must manage the states of blocks that are in the midst of coherence transactions, including situations in which a cache controller receives a forwarded request from another controller in between sending its coherence request to the directory and receiving all of its necessary response messages, including Data and possible Inv-Acks. The cache controllers can maintain this state in the miss status handling registers (MSHRs) that cores use to keep track of outstanding coherence requests. Notationally, we represent these transient states in the form XY^{AD} , where the superscript A denotes waiting for acknowledgments and the superscript D denotes waiting for data. (This notation differs from the snooping protocols, in which the superscript A denoted waiting for a request to appear on the bus.)

TABLE 8.1: MSI Directory Protocol—Cache Controller

	load	store	replacement	Fwd-GetS	Fwd-GetM	Inv	Put-Ack	Data from Dir (ack=0)	Data from Dir (ack>0)	Data from Owner	Inv-Ack	Last-Inv-Ack

M	Send Fwd-GetS to Owner, add Req and Owner to Sharers, clear Owner/S ^D	Send Fwd-GetM to Owner, set Owner to Req	send Put-Ack to Req	send Put-Ack to Req	copy data to memory, clear Owner, send Put-Ack to Req/I	send Put-Ack to Req	
S ^D	stall	stall	remove Req from Sharers, send Put-Ack to Req	remove Req from Sharers, send Put-Ack to Req		remove Req from Sharers, send Put-Ack to Req	copy data to memory/S

Because these tables can be somewhat daunting at first glance, the next section walks through some example scenarios.

8.2.5 Protocol Operation

The protocol enables caches to acquire blocks in states S and M and to replace blocks to the directory in either of these states.

I to S (common case #1)

The cache controller sends a GetS request to the directory and changes the block state from I to IS^D. The directory receives this request and, if the directory is the owner (i.e., no cache currently has the block in M), the directory responds with a Data message, changes the block's state to S (if it is not S already), and adds the requestor to the sharer list. When the Data arrives at the requestor, the cache controller changes the block's state to S, completing the transaction.

I to S (common case #2)

The cache controller sends a GetS request to the directory and changes the block state from I to IS^D. If the directory is *not* the owner (i.e., there is a cache that currently has the block in M), the directory forwards the request to the owner and changes the block's state to the transient state S^D. The owner responds to this Fwd-GetS message by sending Data to the requestor and changing the block's state to S. The now-previous owner must also send Data to the directory since it is relinquishing ownership to the directory, which must have an up-to-date copy of the block. When the

Data arrives at the requestor, the cache controller changes the block state to S and considers the transaction complete. When the Data arrives at the directory, the directory copies it to memory, changes the block state to S, and considers the transaction complete.

I to S (race cases)

The above two I-to-S scenarios represent the common cases, in which there is only one transaction for the block in progress. Most of the protocol's complexity derives from having to deal with the less-common cases of multiple in-progress transactions for a block. For example, a reader may find it surprising that a cache controller can receive an Invalidation for a block in state IS^D . Consider core C1 that issues a GetS and goes to IS^D and another core C2 that issues a GetM for the same block that arrives at the directory after C1's GetS. The directory first sends C1 Data in response to its GetS and then an Invalidation in response to C2's GetM. Because the Data and Invalidation travel on separate networks, they can arrive out of order, and thus C1 can receive the Invalidation before the Data.

I or S to M

The cache controller sends a GetM request to the directory and changes the block's state from I to IM^{AD} . In this state, the cache waits for Data and (possibly) Inv-Acks that indicate that other caches have invalidated their copies of the block in state S. The cache controller knows how many Inv-Acks to expect, since the Data message contains the AckCount, which may be zero. Figure 8.3 illustrates the three common-case scenarios of the directory responding to the GetM request. If the directory is in state I, it simply sends Data with an AckCount of zero and goes to state M. If in state M, the directory controller forwards the request to the owner and updates the block's owner; the now-previous owner responds to the Fwd-GetM request by sending Data with an AckCount of zero. The last common case occurs when the directory is in state S. The directory responds with Data and an AckCount equal to the number of sharers, plus it sends Invalidation to each core in the sharer list. Cache controllers that receive Invalidation messages invalidate their shared copies and send Inv-Acks to the requestor. When the requestor receives the last Inv-Ack, it transitions to state M. Note the special Last-Inv-Ack event in Table 8.1, which simplifies the protocol specification.

These common cases neglect some possible races that highlight the concurrency of directory protocols. For example, core C1 has the cache block in state IM^A and receives a Fwd-GetS from C2's cache controller. This situation is possible because the directory has already sent Data to C1, sent Invalidation messages to the sharers, and changed its state to M. When C2's GetS arrives at the directory, the directory simply forwards it to the owner, C1. This Fwd-GetS may arrive at C1 before all of the Inv-Acks arrive at C1. In this situation, our protocol simply stalls and the cache controller

waits for the Inv-Acks. Because Inv-Acks travel on a separate network, they are guaranteed not to block behind the unprocessed Fwd-GetS.

M to I

To evict a block in state M, the cache controller sends a PutM request that includes the data and changes the block state to MI^A . When the directory receives this PutM, it updates the LLC/memory, responds with a Put-Ack, and transitions to state I. Until the requestor receives the Put-Ack, the block's state remains effectively M and the cache controller must respond to forwarded coherence requests for the block. In the case where the cache controller receives a forwarded coherence request (Fwd-GetS or Fwd-GetM) between sending the PutM and receiving the Put-Ack, the cache controller responds to the Fwd-GetS or Fwd-GetM and changes its block state to SI^A or II^A , respectively. These transient states are effectively S and I, respectively, but denote that the cache controller must wait for a Put-Ack to complete the transition to I.

S to I

Unlike the snooping protocols in the previous chapter, our directory protocols do not silently evict blocks in state S. Instead, to replace a block in state S, the cache controller sends a PutS request and changes the block state to SI^A . The directory receives this PutS and responds with a Put-Ack. Until the requestor receives the Put-Ack, the block's state is effectively S. If the cache controller receives an Invalidation request after sending the PutS and before receiving the Put-Ack, it changes the block's state to II^A . This transient state is effectively I, but it denotes that the cache controller must wait for a Put-Ack to complete the transaction from S to I.

8.2.6 Protocol Simplifications

This protocol is relatively straightforward and sacrifices some performance to achieve this simplicity. We now discuss two simplifications:

- The most significant simplification, other than having only three stable states, is that the protocol stalls in certain situations. For example, a cache controller stalls when it receives a forwarded request while in a transient state. A higher performance option, discussed in Section 8.7.2, would be to process the messages and add more transient states.
- A second simplification is that the directory sends Data (and the AckCount) in response to a cache that is changing a block's state from S to M. The cache already has valid data and thus it would be sufficient for the directory to simply send a data-less AckCount. We defer adding this new type of message until we present the MOSI protocol in Section 8.4.

8.3 ADDING THE EXCLUSIVE STATE

As we previously discussed in the context of snooping protocols, adding the Exclusive (E) state is an important optimization because it enables a core to read and then write a block with only a single coherence transaction, instead of the two required by an MSI protocol. At the highest level, this optimization is independent of whether the cache coherence uses snooping or directories. If a core issues a GetS and the block is not currently shared by other cores, then the requestor may obtain the block in state E. The core may then silently upgrade the block's state from E to M without issuing another coherence request.

In this section, we add the E state to our baseline MSI directory protocol. As with the MESI snooping protocol in the previous chapter, the operation of the protocol depends on whether the E state is considered an ownership state or not. And, as with the MESI snooping protocol, the primary operational difference involves determining which coherence controller should respond to a request for a block that the directory gave to a cache in state E. The block may have been silently upgraded from E to M since the directory gave the block to the cache in state E.

In protocols in which an E block is owned, the solution is simple. The cache with the block in E (or M) is the owner and thus must respond to requests. A coherence request sent to the directory will be forwarded to the cache with the block in state E. Because the E state is an ownership state, the eviction of an E block cannot be performed silently; the cache must issue a PutE request to the directory. Without an explicit PutE, the directory would not know that the directory was now the owner and should respond to incoming coherence requests. Because we assume in this primer that blocks in E are owned, this simple solution is what we implement in the MESI protocol in this section.

In protocols in which an E block is not owned, an E block can be silently evicted, but the protocol complexity increases. Consider the case where core C1 obtains a block in state E and then the directory receives a GetS or GetM from core C2. The directory knows that C1 is either i) still in state E, ii) in state M (if C1 did a store with a silent upgrade from E to M), or iii) in state I (if the protocol allows C1 to perform a silent PutE). If C1 is in M, the directory must forward the request to C1 so that C1 can supply the latest version of the data. If C1 is in E, C1 or the directory may respond since they both have the same data. If C1 is in I, the directory must respond. One solution, which we describe in more detail in our case study on the SGI Origin [10] in Section 8.8.1, is to have both C1 and the directory respond. Another solution is to have the directory forward the request to C1. If C1 is in I, C1 notifies the directory to respond to C2; else, C1 responds to C2 and notifies the directory that it does not need to respond to C2.

8.3.1 High-Level Protocol Specification

We specify a high-level view of the transactions in Figure 8.6, with differences from the MSI protocol highlighted. There are only two significant differences. First, there is a transition from I to E

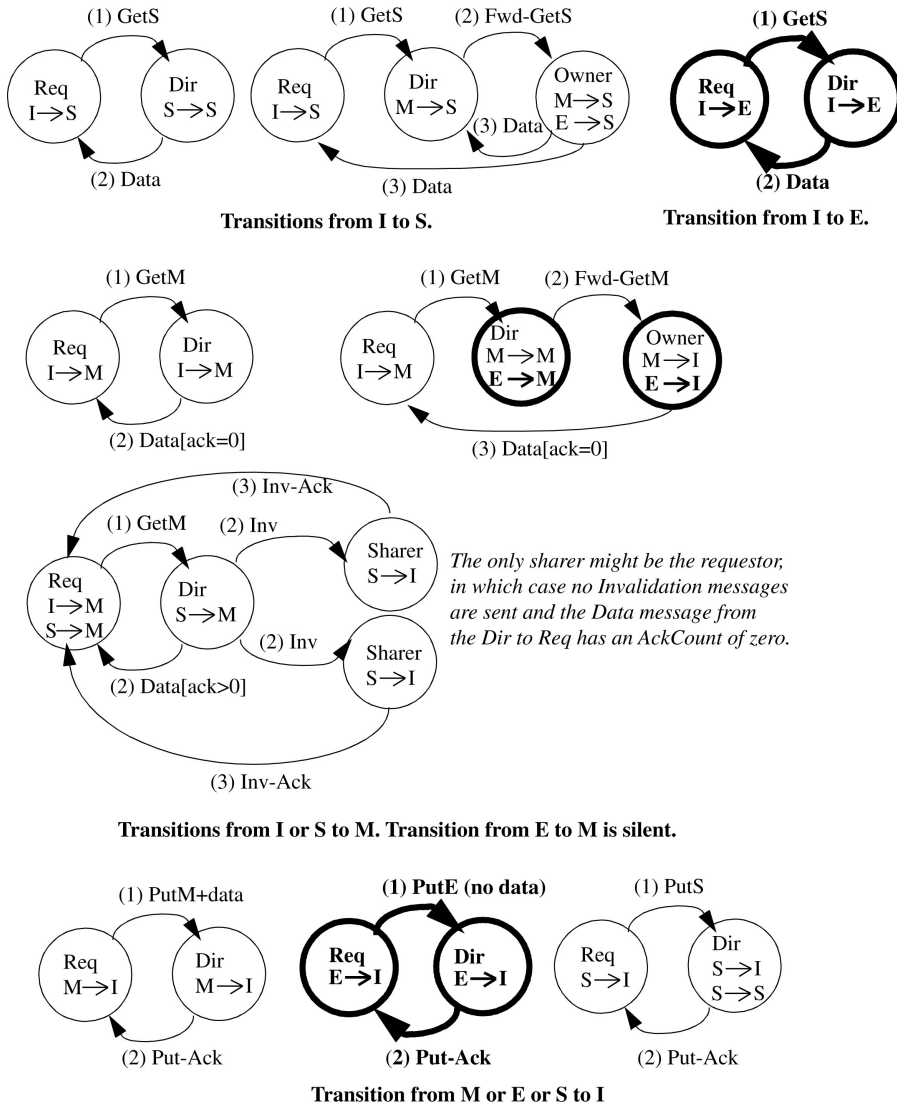

FIGURE 8.6: High-Level Description of MESI Directory Protocol. In each transition, the cache controller that requests the transaction is denoted “Req”.

that can occur if the directory receives a GetS for a block in state I. Second, there is a PutE transaction for evicting blocks in state E. Because E is an ownership state, an E block cannot be silently evicted. Unlike a block in state M, the E block is clean, and thus the PutE does not need to carry data; the directory already has the most up-to-date copy of the block.

8.3.2 Detailed Protocol Specification

In Tables 8.3 and 8.4, we present the detailed specification of the MESI protocol, including transient states. Differences with respect to the MSI protocol are highlighted with boldface font. The protocol adds to the set of cache states both the stable E state as well as transient states to handle transactions for blocks initially in state E.

This protocol is somewhat more complex than the MSI protocol, with much of the added complexity at the directory controller. In addition to having more states, the directory controller must distinguish between more possible events. For example, when a PutS arrives, the directory must distinguish whether this is the “last” PutS; that is, did this PutS arrive from the only current sharer? If this PutS is the last PutS, then the directory’s state changes to I.

8.4 ADDING THE OWNED STATE

For the same reason we added the Owned state to the baseline MSI snooping protocol in Chapter 7, an architect may want to add the Owned state to the baseline MSI directory protocol presented in Section 8.2. Recall from Chapter 2 that if a cache has a block in the Owned state, then the block is valid, read-only, dirty (i.e., it must eventually update memory), and owned (i.e., the cache must respond to coherence requests for the block). Adding the Owned state changes the protocol, compared to MSI, in three important ways: (1) a cache with a block in M that observes a Fwd-GetS changes its state to O and does not need to (immediately) copy the data back to the LLC/memory, (2) more coherence requests are satisfied by caches (in O state) than by the LLC/memory, and (3) there are more 3-hop transactions (which would have been satisfied by the LLC/memory in an MSI protocol).

8.4.1 High-Level Protocol Specification

We specify a high-level view of the transactions in Figure 8.7, with differences from the MSI protocol highlighted. The most interesting difference is the transaction in which a requestor of a block in state I or S sends a GetM to the directory when the block is in the O state in the owner cache and in the S state in one or more sharer caches. In this case, the directory forwards the GetM to the owner,

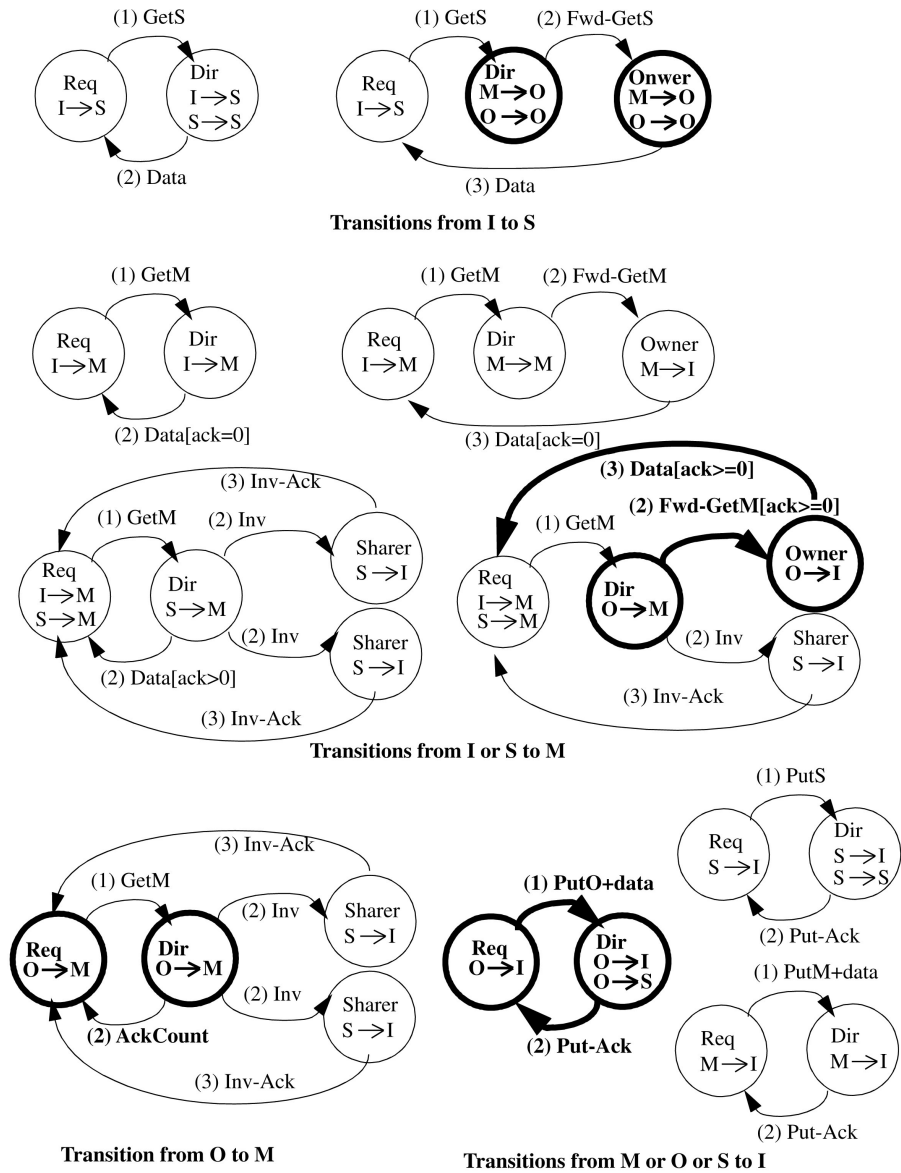

FIGURE 8.7: High-Level Description of MOSI Directory Protocol. In each transition, the cache controller that requests the transaction is denoted “Req”.

and appends the AckCount. The directory also sends Invalidations to each of the sharers. The owner receives the Fwd-GetM and responds to the requestor with Data and the AckCount. The requestor uses this received AckCount to determine when it has received the last Inv-Ack. There is a similar transaction if the requestor of the GetM was the owner (in state O). The difference here is that the directory sends the AckCount directly to the requestor because the requestor is the owner.

This protocol has a PutO transaction that is nearly identical to the PutM transaction. It contains data for the same reason that the PutM transaction contains data, i.e., because both M and O are dirty states.

8.4.2 Detailed Protocol Specification

Tables 8.5 and 8.6 present the detailed specification of the MOSI protocol, including transient states. Differences with respect to the MSI protocol are highlighted with boldface font. The protocol adds to the set of cache states both the stable O state as well as transient OM^{AC} , OM^A , and

OI^A states to handle transactions for blocks initially in state O. The state OM^{AC} indicates that the cache is waiting for both Inv-Acks (A) from caches and an AckCount (C) from the directory, but not data. Because this block started in state O, it already had valid data.

An interesting situation arises when core C1's cache controller has a block in OM^{AC} or SM^{AD} and receives a Fwd-GetM or Invalidation from core C2 for that block. C2's GetM must have been ordered at the directory before C1's GetM, for this situation to arise. Thus, the directory state changes to M (owned by C2) before observing C1's GetM. When C2's Fwd-GetM or Invalidation arrives at C1, C1 must be aware that C2's GetM was ordered first. Thus, C1's cache state changes from either OM^{AC} or SM^{AD} to IM^{AD}. The forwarded GetM or Invalidation from C2 invalidated C1's cache block and now C1 must wait for both Data and Inv-Acks.

8.5 REPRESENTING DIRECTORY STATE

In the previous sections, we have assumed a *complete directory*, that is, the directory maintains the complete state for each block, including the full set of caches that (may) have shared copies. Yet this assumption contradicts the primary motivation for directory protocols: scalability. In a system with a large number of caches (i.e., a large number of potential sharers of a block), maintaining the complete set of sharers for each block requires a significant amount of storage, even when using a compact bit-vector representation. For a system with a modest number of caches, it may be reason-

able to maintain this complete set, but the architects of larger-scale systems may wish for more scalable solutions to maintaining directory state.

There are many ways to reduce how much state the directory maintains for each block. Here we discuss two important techniques: coarse directories and limited pointers. We discuss these techniques independently, but observe that they can be combined. We contrast each solution with the baseline design, illustrated in the top entry of Figure 8.8.

8.5.1 Coarse Directory

Having the complete set of sharers enables the directory to send Invalidation messages to exactly those cache controllers that have the block in state S. One way to reduce the directory state is to conservatively maintain a coarse list of sharers that is a superset of the actual set of sharers. That is, a given entry in the sharer list corresponds to a set of K caches, as illustrated in the middle entry of Figure 8.8. If one or more of the caches in that set (may) have the block in state S, then that bit in the sharer list is set. A GetM will cause the directory controller to send an Invalidation to all K caches in that set. Thus, coarse directories reduce the directory state at the expense of extra inter-connection network bandwidth for unnecessary Invalidation messages, plus the cache controller bandwidth to process these extra Invalidation messages.

8.5.2 Limited Pointer Directory

In a chip with C caches, a complete sharer list requires C entries, one bit each, for a total of C bits. However, studies have shown that many blocks have zero sharers or one sharer. A limited pointer directory exploits this observation by having i ($i < C$) entries, where each entry requires $\log_2 C$ bits, for a total of $i * \log_2 C$ bits, as illustrated in the bottom entry of Figure 8.8. A limited pointer directory

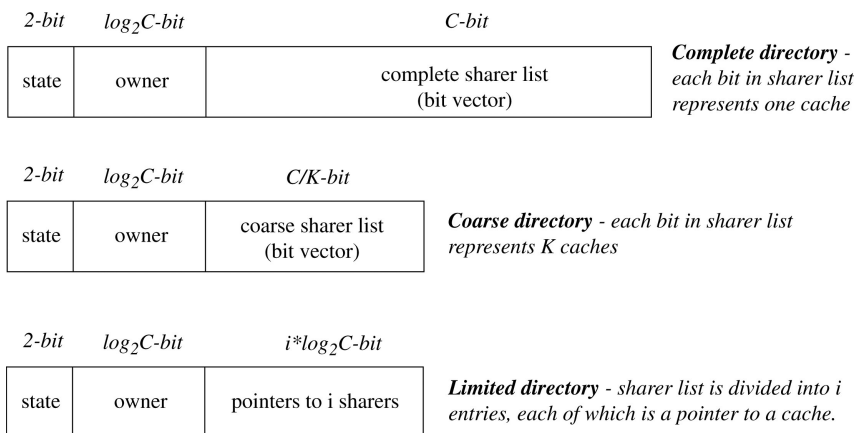

FIGURE 8.8: Representing directory state for a block in a system with N nodes.

requires some additional mechanism to handle (hopefully uncommon) situations in which the system attempts to add an $i+1^{th}$ sharer. There are three well-studied options for handling these situations, denoted using the notation Dir_iX [2, 8], where i refers to the number of pointers to sharers, and X refers to the mechanism for handling situations in which the system attempts to add an $i+1^{th}$ sharer.

- **Broadcast (Dir_iB):** If there are already i sharers and another GetS arrives, the directory controller sets the block's state to indicate that a subsequent GetM requires the directory to broadcast the Invalidation to all caches (i.e., a new “too many sharers” state). A drawback of Dir_iB is that the directory could have to broadcast to all C caches even when there are only K sharers ($i < K < C$), requiring the directory controller to send (and the cache controllers to process) $C-K$ unnecessary Invalidation messages. The limiting case, Dir_0B , takes this approach to the extreme by eliminating all pointers and requiring a broadcast on all coherence operations. The original Dir_0B proposal maintained two state bits per block, encoding the three MSI states plus a special “Single Sharer” state [3]. This new state helps eliminate a broadcast when a cache tries to upgrade its S copy to an M copy (similar to the Exclusive state optimization). Similarly, the directory's I state eliminates broadcast when memory owns the block. AMD's Coherent HyperTransport [6] implements a version of Dir_0B that uses no directory state, forgoing these optimizations but eliminating the need to store any directory state. All requests sent to the directory are then broadcast to all caches.
- **No Broadcast (Dir_iNB):** If there are already i sharers and another GetS arrives, the directory asks one of the current sharers to invalidate itself to make room in the sharer list for the new requestor. This solution can incur significant performance penalties for widely-shared blocks (i.e., blocks shared by more than i nodes), due to the time spent invalidating sharers. Dir_iNB is especially problematic for systems with coherent instruction caches because code is frequently widely shared.
- **Software (Dir_iSW):** If there are already i sharers and another GetS arrives, the system traps to a software handler. Trapping to software enables great flexibility, such as maintaining a full sharer list in software-managed data structures. However, because trapping to software incurs significant performance costs and implementation complexities, this approach has seen limited commercial acceptance.

8.6 DIRECTORY ORGANIZATION

Logically, the directory contains a single entry for every block of memory. Many traditional directory-based systems, in which the directory controller was integrated with the memory controller, directly implemented this logical abstraction by augmenting memory to hold the directory. For

example, the SGI Origin added additional DRAM chips to store the complete directory state with each block of memory [10].

However, with today's multicore processors and large LLCs, the traditional directory design makes little sense. First, architects do not want the latency and power overhead of a directory access to off-chip memory, especially for data cached on chip. Second, system designers balk at the large off-chip directory state when almost all memory blocks are not cached at any given time. These drawbacks motivate architects to optimize the common case by caching only a subset of directory entries on chip. In the rest of this section, we discuss directory cache designs, several of which were previously categorized by Marty and Hill [13].

Like conventional instruction and data caches, a directory cache [7] provides faster access to a subset of the complete directory state. Because directories summarize the states of coherent caches, they exhibit locality similar to instruction and data accesses, but need only store each block's coherence state rather than its data. Thus, relatively small directory caches achieve high hit rates. Directory caching has no impact on the functionality of the coherence protocol; it simply reduces the average directory access latency. Directory caching has become even more important in the era of multicore processors. In older systems in which cores resided on separate chips and/or boards, message latencies were sufficiently long that they tended to amortize the directory access latency. Within a multicore processor, messages can travel from one core to another in a handful of cycles, and the latency of an off-chip directory access tends to dwarf communication latencies and become a bottleneck. Thus, for multicore processors, there is a strong incentive to implement an on-chip directory cache to avoid costly off-chip accesses.

The on-chip directory cache contains a subset of the complete set of directory entries. Thus, the key design issue is handling directory cache misses, i.e., when a coherence request arrives for a block whose directory entry is not in the directory cache.

We summarize the design options in Table 8.7 and describe them next.

8.6.1 Directory Cache Backed by DRAM

The most straightforward design is to keep the complete directory in DRAM, as in traditional multi-chip multiprocessors, and use a separate directory cache structure to reduce the average access latency. A coherence request that misses in this directory cache leads to an access of this DRAM directory. This design, while straightforward, suffers from several important drawbacks. First, it requires a significant amount of DRAM to hold the directory, including state for the vast majority of blocks that are not currently cached on the chip. Second, because the directory cache is decoupled from the LLC, it is possible to hit in the LLC but miss in the directory cache, thus incurring a DRAM access even though the data is available locally. Finally, directory cache replacements must write the directory entries back to DRAM, incurring high latency and power overheads.

TABLE 8.7: Comparing Directory Cache Designs

TABLE 8.7: Comparing Directory Cache Designs						
		Inclusive directory caches (Section 8.6.2)				
	Directory cache backed by DRAM directory (Section 8.6.1)	Inclusive directory cache embedded in inclusive LLC (Section 8.6.2.1)		Standalone inclusive directory cache (Section 8.6.2.2)		Null Directory Cache (Section 8.6.3)
		No Recalls	With Recalls	No Recalls	With Recalls	
directory location	DRAM	LLC		LLC		none
uses DRAM	yes	no		no		no
miss at directory implies	must access DRAM	block must be I		block must be I		block could be in any state → must broadcast
inclusion requirements	none	LLC includes L1s		directory cache includes L1s		none
implementation costs	DRAM plus separate on-chip cache	larger LLC blocks; highly associative LLC	larger LLC blocks	highly associative storage for redundant tags	storage for redundant tags	none
replacement notification	none	none	desirable	required	desirable	none

8.6.2 Inclusive Directory Caches

We can design directory caches that are more cost-effective by exploiting the observation that we need only cache directory states for blocks that are being cached on the chip. We refer to a directory cache as an *inclusive directory cache* if it holds directory entries for a superset of all blocks cached on the chip. An inclusive directory cache serves as a “perfect” directory cache that never misses for accesses to blocks cached on chip. There is no need to store a complete directory in DRAM. A miss in an inclusive directory cache indicates that the block is in state I; a miss is *not* the precursor to accessing some backing directory store.

We now discuss two inclusive directory cache designs, plus an optimization that applies to both designs.

8.6.2.1 Inclusive Directory Cache Embedded in Inclusive LLC

The simplest directory cache design relies on an LLC that maintains *inclusion* with the upper-level caches. Cache inclusion means that if a block is in an upper-level cache then it must also be present in a lower-level cache. For the system model of Figure 8.1, LLC inclusion means that if a block is in a core’s L1 cache, then it must also be in the LLC.

A consequence of LLC inclusion is that if a block is *not* in the LLC, it is also *not* in an L1 cache and thus must be in state I for all caches on the chip. An inclusive directory cache exploits this property by embedding the coherence state of each block in the LLC. If a coherence request is sent to the LLC/directory controller and the requested address is not present in the LLC, then the directory controller knows that the requested block is not cached on-chip and thus is in state I in all the L1s.

Because the directory mirrors the contents of the LLC, the entire directory cache may be embedded in the LLC simply by adding extra bits to each block in the LLC. These added bits can lead to non-trivial overhead, depending on the number of cores and the format in which directory state is represented. We illustrate the addition of this directory state to an LLC cache block in Figure 8.9, comparing it to an LLC block in a system without the LLC-embedded directory cache.

Unfortunately, LLC inclusion has several important drawbacks. First, while LLC inclusion can be maintained automatically for private cache hierarchies (if the lower-level cache has sufficient associativity [4]), for the shared caches in our system model, it is generally necessary to send special “Recall” requests to invalidate blocks from the L1 caches when replacing a block in the LLC (discussed further in Section 8.6.2.3). More importantly, LLC inclusion requires maintaining redundant copies of cache blocks that are in upper-level caches. In multicore processors, the collective capacity of the upper-level caches may be a significant fraction of (or sometimes, even larger than) the capacity of the LLC.

8.6.2.2 Standalone Inclusive Directory Cache

We now present an inclusive directory cache design that does not rely on LLC inclusion. In this design, the directory cache is a standalone structure that is logically associated with the directory controller, instead of being embedded in the LLC itself. For the directory cache to be inclusive, it must contain directory entries for the union of the blocks in all the L1 caches because a block in the LLC but not in any L1 cache must be in state I. Thus, in this design, the directory cache consists of duplicate copies of the tags at all L1 caches. Compared to the previous design (Section 8.6.2.1),

FIGURE 8.9: The cost of implementing the LLC-embedded directory cache

this design is more flexible, by virtue of not requiring LLC inclusion, but it has the added storage cost for the duplicate tags.

This inclusive directory cache has some significant implementation costs. Most notably, it requires a highly associative directory cache. (If we embed the directory cache in an inclusive LLC (Section 8.6.2.1), then the LLC must also be highly associative.) Consider the case of a chip with C cores, each of which has a K -way set-associative L1 cache. The directory cache must be $C \cdot K$ -way associative to hold all L1 cache tags, and the associativity unfortunately grows linearly with core count. We illustrate this issue for $K=2$ in Figure 8.10.

The inclusive directory cache design also introduces some complexity, in order to keep the directory cache up-to-date. When a block is evicted from an L1 cache, the cache controller must notify the directory cache regarding which block was replaced by issuing an explicit PutS request (e.g., we cannot use a protocol with a silent eviction, as discussed in Section 8.7.4). One common optimization is to piggy-back the explicit PutS on the GetS or GetX request. Since the index bits must be the same, the PutS can be encoded by specifying which way was replaced. This is sometimes referred to as a “replacement hint,” although in general it is required (and not truly a “hint”).

8.6.2.3 Limiting the Associativity of Inclusive Directory Caches

To overcome the cost of the highly-associative directory cache in the previous implementation, we present a technique for limiting its associativity. Rather than design the directory cache for the worst-case situation ($C \cdot K$ associativity), we limit the associativity by not permitting the worst-case to occur. That is, we design the directory cache to be A -way set associative, where $A < C \cdot K$, and we do not permit more than A entries that map to a given directory cache set to be cached on chip. When a cache controller issues a coherence request to add a block to its cache, and the corresponding set in the directory cache is already full of valid entries, then the directory controller first evicts one of the blocks in this set from all caches. The directory controller performs this eviction by issu-

	core 0		core 1		core C-1	
set 0	set 0	set 0	set 0	set 0	set 0	set 0
	way 0	way 1	way 0	way 1	way 0	way 1
	set 1	set 1	set 1	set 1	set 1	set 1
	way 0	way 1	way 0	way 1	way 0	way 1
	⋮	⋮	⋮	⋮	⋮	⋮
	⋮	⋮	⋮	⋮	⋮	⋮
	⋮	⋮	⋮	⋮	⋮	⋮
set S-1	set S-1	set S-1	set S-1	set S-1	set S-1	set S-1
	way 0	way 1	way 0	way 1	way 0	way 1

FIGURE 8.10: Inclusive directory cache structure (assumes 2-way L1 caches). Each entry is the tag corresponding to that set and way for the core at the top of the column.

ing a “Recall” request to all of the caches that hold this block in a valid state, and the caches respond with acknowledgments. Once an entry in the directory cache has been freed up via this Recall, then the directory controller can process the original coherence request that triggered the Recall.

The use of Recalls overcomes the need for high associativity in the directory cache but, without careful design, it could lead to poor performance. If the directory cache is too small, then Recalls will be frequent and performance will suffer. Conway et al. [6] propose a rule of thumb that the directory cache should cover at least the size of the aggregate caches it includes, but it can also be larger to reduce the rates of recalls. Also, to avoid unnecessary Recalls, this scheme works best with non-silent evictions of blocks in state S. With silent evictions, unnecessary Recalls will be sent to caches that no longer hold the block being recalled.

8.6.3 Null Directory Cache (with no backing store)

The least costly directory cache is to have no directory cache at all. Recall that the directory state helps prune the set of coherence controllers to which to forward a coherence request. But as with Coarse Directories (Section 8.5.1), if this pruning is done incompletely, the protocol still works correctly, but unnecessary messages are sent and the protocol is less efficient than it could be. Taken to the extreme, a Dir₀B protocol (Section 8.5.2) does no pruning whatsoever, in which case it does not actually need a directory at all (or a directory cache). Whenever a coherence request arrives at the directory controller, the directory controller simply forwards it to all caches (i.e., broadcasts the forwarded request). This directory cache design, which we call the Null Directory Cache, may seem simplistic, but it is popular for small- to medium-scale systems because it incurs no storage cost.

One might question the purpose of a directory controller if there is no directory state, but it serves two important roles. First, as with all other systems in this chapter, the directory controller is responsible for the LLC; it is, more precisely, an LLC/directory controller. Second, the directory controller serves as an ordering point in the protocol; if multiple cores concurrently request the same block, the requests are ordered at the directory controller. The directory controller resolves which request happens first.

8.7 PERFORMANCE AND SCALABILITY OPTIMIZATIONS

In this section, we discuss several optimizations to improve the performance and scalability of directory protocols.

8.7.1 Distributed Directories

So far we have assumed that there is a single directory attached to a single monolithic LLC. This design clearly has the potential to create a performance bottleneck at this shared, central resource.

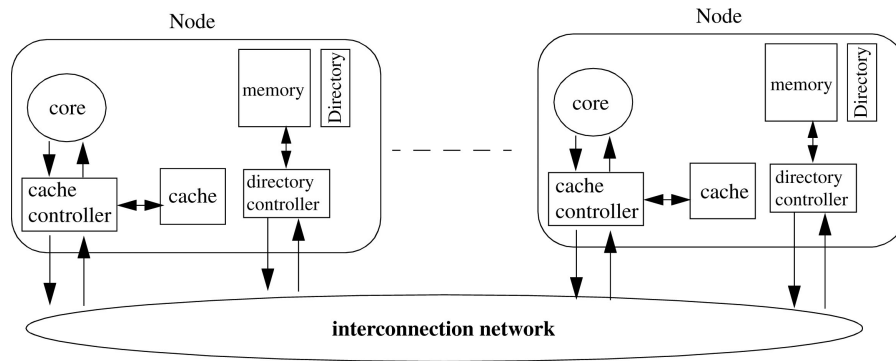

FIGURE 8.11: Multiprocessor system model with distributed directory.

The typical, general solution to the problem of a centralized bottleneck is to distribute the resource. The directory for a given block is still fixed in one place, but different blocks can have different directories.

In older, multi-chip multiprocessors with N nodes—each node consisting of multiple chips, including the processor core and memory—each node typically had $1/N$ of the memory associated with it and the corresponding $1/N^{\text{th}}$ of the directory state.

We illustrate such a system model in Figure 8.11. The allocation of memory addresses to nodes is often static and often easily computable using simple arithmetic. For example, in a system with N directories, block B 's directory entry might be at directory $B \bmod N$. Each block has a *home*, which is the directory that holds its memory and directory state. Thus, we end up with a system in which there are multiple, independent directories managing the coherence for different sets of blocks. Having multiple directories provides greater bandwidth of coherence transactions than requiring all coherence traffic to pass through a single, central resource. Importantly, distributing the directory has no impact on the coherence protocol.

In today's world of multicore processors with large LLCs and directory caches, the approach of distributing the directory is logically the same as in the traditional multi-chip multiprocessors. We can distribute (bank) the LLC and directory cache. Each block has a home bank of the LLC with its associated bank of the directory cache.

8.7.2 Non-Stalling Directory Protocols

One performance limitation of the protocols presented thus far is that the coherence controllers stall in several situations. In particular, the cache controllers stall when they receive forwarded requests for blocks in certain transient states, such as IM^A . In Tables 8.8 and 8.9, we present a variant of the baseline MSI protocol that does not stall in these scenarios. For example, when a cache

TABLE 8.8: Non-stalling MSI Directory Protocol—Cache Controller

	load	store	replacement	Fwd-GetS	Fwd-GetM	Inv	Put-Ack	Data from Dir (ack=0)	Data from Dir (ack>0)	Data from Owner	Inv-Ack	Last-Inv-Ack
I	send GetS to Dir/IS ^D	send GetM to Dir/IM ^{AD}										
IS ^D	stall	stall	stall			send Inv-Ack to Req/IS ^D I		-/S		-/S		
IS ^D I	stall	stall	stall					-/I		-/I		
IM ^{AD}	stall	stall	stall	stall	stall			-/M	-/IM ^A	-/M	ack--	
IM ^A	stall	stall	stall	-/IM ^{AS}	-/IM ^{AI}						ack--	-/M
IM ^{AS}	stall	stall	stall			send Inv-Ack to Req/IM ^{ASI}					ack--	send data to Req and Dir/S
IM ^{ASI}	stall	stall	stall								ack--	send data to Req and Dir/I
IM ^{AI}	stall	stall	stall								ack--	send data to Req/I
S	hit	send GetM to Dir/SM ^{AD}	send PutS to Dir/SI ^A			send Inv-Ack to Req/I						
SM ^{AD}	hit	stall	stall	stall	stall	send Inv-Ack to Req/IM ^{AD}		-/M	-/SM ^A	-/M	ack--	
SM ^A	hit	stall	stall	-/SM ^{AS}	-/SM ^{AI}						ack--	-/M
SM ^{AS}	stall	stall	stall			send Inv-Ack to Req/SM ^{ASI}					ack--	send data to Req and Dir/S
SM ^{ASI}	stall	stall	stall								ack--	send data to Req and Dir/I
SM ^{AI}	stall	stall	stall								ack--	send data to Req/I
M	hit	hit	send PutM+data to Dir/MI ^A	send data to Req and Dir/S	send data to Req/I							
MI ^A	stall	stall	stall	send data to Req and Dir/SI ^A	send data to Req/II ^A		-/I					
SI ^A	stall	stall	stall			send Inv-Ack to Req/II ^A	-/I					
II ^A	stall	stall	stall				-/I					

controller has a block in state IM^A and receives a Fwd-GetS, it processes the request and changes the block's state to IM^{AS}. This state indicates that after the cache controller's GetM transaction completes (i.e., when the last Inv-Ack arrives), the cache controller will change the block state to S. At this point, the cache controller must also send the block to the requestor of the GetS and to the directory, which is now the owner. By not stalling on the Fwd-GetS, the cache controller can improve performance by continuing to process other forwarded requests behind that Fwd-GetS in its incoming queue.

TABLE 8.9: Non-stalling MSI Directory Protocol—Directory Controller

	GetS	GetM	PutS-NotLast	PutS-Last	PutM+data from Owner	PutM+data from NonOwner	Data
I	send data to Req, add Req to Sharers/S	send data to Req, set Owner to Req/M	send Put-Ack to Req	send Put-Ack to Req		send Put-Ack to Req	
S	send data to Req, add Req to Sharers	send data to Req, set Owner to Req, send Inv to Sharers, clear Sharers/M	send Put-Ack to Req, remove Req from Sharers	send Put-Ack to Req, remove Req from Sharers/I		remove Req from Sharers, send Put-Ack to Req	
M	forward GetS to Owner, add Req to Sharers, clear Owner/S ^D	forward GetM to Owner, set Owner to Req	send Put-Ack to Req	send Put-Ack to Req	copy data to memory, send Put-Ack to Req, clear Owner/I	send Put-Ack to Req	
S ^D	stall	stall	send Put-Ack to Req, remove Req from Sharers	send Put-Ack to Req, remove Req from Sharers		remove Req from Sharers, send Put-Ack to Req	copy data to memory/S

A complication in the non-stalling protocol is that, while in state IM^AS , a Fwd-GetM could arrive. Instead of stalling, the cache controller processes this request and changes the block's state to IM^ASI (in I, going to M, waiting for Inv-Acks, then will go to S and then to I). A similar set of transient states arises for blocks in SM^A . Removing stalling leads to more transient states, in general, because the coherence controller must track (using new transient states) the additional messages it is processing instead of stalling.

We did not remove the stalls from the directory controller. As with the memory controllers in the snooping protocols in Chapter 7, we would need to add an impractically large number of transient states to avoid stalling in all possible scenarios.

8.7.3 Interconnection Networks Without Point-to-Point Ordering

We mentioned in Section 8.2, when discussing the system model of our baseline MSI directory protocol, that we assumed that the interconnection network provides point-to-point ordering for the Forwarded Request network. At the time, we claimed that point-to-point ordering simplifies the architect's job in designing the protocol because ordering eliminates the possibility of certain races.

We now present one example race that is possible if we do not have point-to-point ordering in the interconnection network. We assume the MOSI protocol from Section 8.4. Core C1's cache owns a block in state M. Core C2 sends a GetS request to the directory and core C3 sends a GetM request to the directory. The directory receives C2's GetS first and then C3's GetM. For both requests, the directory forwards them to C1.

FIGURE 8.12: Example with point-to-point ordering.

- With point-to-point ordering (illustrated in Figure 8.12): C1 receives the Fwd-GetS, responds with Data, and changes the block state to O. C1 then receives the Fwd-GetM, responds with Data, and changes the block state to I. This is the expected outcome.
- Without point-to-point ordering (illustrated in Figure 8.13): The Fwd-GetM from C3 may arrive at C1 first. C1 responds with Data to C3 and changes the block state to I. The Fwd-GetS from C2 then arrives at C1. C1 is in I and cannot respond. The GetS request from C2 will never be satisfied and the system will eventually deadlock.

The directory protocols we have presented thus far are not compatible with interconnection networks that do not provide point-to-point order for the Forwarded Request network. To make the protocols compatible, we would have to modify them to correctly handle races like the one described above. One typical approach to eliminating races like these is to add extra handshaking messages. In the example above, the directory could wait for the cache controller to acknowledge reception of each forwarded request sent to it before forwarding another request to it.

FIGURE 8.13: Example without point-to-point ordering. Note that C2's Fwd-GetS arrives at C1 in state I and thus C1 does not respond.

FIGURE 8.14: Adaptive Routing Example.

Given that point-to-point ordering reduces complexity, it would seem an obvious design decision. However, enforcing point-to-point ordering prohibits us from implementing some potentially useful optimizations in the interconnection network. Notably, it prohibits the unrestricted use of adaptive routing.

Adaptive routing enables a message to dynamically choose its path as it traverses the network, generally to avoid congested links or switches. Adaptive routing, although useful for spreading traffic and mitigating congestion, enables messages between endpoints to take different paths and thus arrive in a different order than that in which they were sent. Consider the example in Figure 8.14, in which Switch A sends two messages, M1 and then M2, to Switch D. With adaptive routing, they take different paths, as shown in the figure. If there happens to be more congestion at Switch B than at Switch C, then M2 could arrive at Switch D before M1, despite being sent after M1.

8.7.4 Silent vs. Non-Silent Evictions of Blocks in State S

We designed our baseline directory protocol such that a cache cannot silently evict a block in state S (i.e., without issuing a PutS to notify the directory). To evict an S block, the cache must send a PutS to the directory and wait for a Put-Ack. Another option would be to allow silent evictions of S blocks. (A similar discussion could be made for blocks in state E, if one considers the E state to not be an ownership state, in which case silent evictions of E blocks are possible.)

Advantages of Silent PutS

The drawback to the explicit PutS is that it uses interconnection network bandwidth—albeit for small data-free PutS and Put-Ack messages—even in cases when it ends up not being helpful. For example if core C1 sends a PutS to the directory and then subsequently wants to perform a load to this block, C1 sends a GetS to the directory and re-acquires the block in S. If C1 sends this second

GetS before any intervening GetM requests from other cores, then the PutS transaction served no purpose but did consume bandwidth.

Advantages of Explicit PutS

The primary motivation for sending a PutS is that a PutS enables the directory to remove the cache no longer sharing the block from its list of sharers. There are three benefits to having a more precise sharer list. First, when a subsequent GetM arrives, the directory need not send an Invalidation to this cache. The GetM transaction is accelerated by eliminating the Invalidation and having to wait for the subsequent Inv-Ack. Second, in a MESI protocol, if the directory is precisely counting the sharers, it can identify situations in which the last sharer has evicted its block; when the directory knows there are no sharers, it can respond to a GetS with Exclusive data. Third, recall from Section 8.6.2 that directory caches that use Recalls can benefit from having explicit PutS messages to avoid unnecessary Recall requests.

A secondary motivation for sending a PutS, and the reason our baseline protocol does send a PutS, is that it simplifies the protocol by eliminating some races. Notably, without a PutS, a cache that silently evicts a block in S and then sends a GetS request to re-obtain that evicted block in S can receive an Invalidation from the directory before receiving the data for its GetS. In this situation, the cache does not know if the Invalidation pertains to the first period in which it held the block in S or the second period (i.e., whether the Invalidation is serialized before or after the GetS). The simplest solution to this race is to pessimistically assume the worst case (the Invalidation pertains to the second period) and always invalidate the block as soon as its data arrives. More efficient solutions exist, but complicate the protocol.

8.8 CASE STUDIES

In this section, we discuss several commercial directory coherence protocols. We start with a traditional multi-chip system, the SGI Origin 2000. We then discuss more recently developed directory protocols, including AMD's Coherent HyperTransport and the subsequent HyperTransport Assist. Last, we present Intel's QuickPath Interconnect (QPI).

8.8.1 SGI Origin 2000

The Silicon Graphics Origin 2000 [10] was a commercial multi-chip multiprocessor designed in the mid-1990s to scale to 1024 cores. The emphasis on scalability necessitated a scalable coherence protocol, resulting in one of the first commercial shared-memory systems using a directory protocol. The Origin's directory protocol evolved from the design of the Stanford DASH multiprocessor [11], as the DASH and Origin had overlapping architecture teams.

FIGURE 8.15: SGI Origin.

As illustrated in Figure 8.15, the Origin consists of up to 512 nodes, where each node consists of two MIPS R10000 processors connected via a bus to a specialized ASIC called the Hub. Unlike similar designs, Origin's processor bus does not exploit coherent snooping and simply connects the processors to each other and to the node's Hub. The Hub manages the cache coherence protocol and interfaces the node to the interconnection network. The Hub also connects to the node's portion of the distributed memory and directory. The network does not support any ordering, even point-to-point ordering between nodes. Thus, if Processor A sends two messages to Processor B, they may arrive in a different order than that in which they were sent.

The Origin's directory protocol has a few distinguishing features that are worth discussing. First, because of its scalability, each directory entry contains fewer bits than necessary to represent every possible cache that could be sharing a block. The directory dynamically chooses, for each directory entry, to use either a coarse bit vector representation or a limited pointer representation (Section 8.5).

A second interesting feature in the protocol is that because the network provides no ordering, there are several new coherence message race conditions that are possible. Notably, the examples from Section 8.7.3 are possible. To maintain correctness, the protocol must consider all of these possible race conditions introduced by not enforcing ordering in the network.

A third interesting feature is the protocol's use of a non-ownership E state. Because the E state is not an ownership state, a cache can silently evict a block in state E (or state S). The Origin provides a special Upgrade coherence request to transition from S to E without needlessly requesting data, which is not unusual but does introduce a new race. There is a window of vulnerability between when processor P1 sends an Upgrade and when the Upgrade is serialized at the directory; if another processor's GetM or Upgrade is serialized first, then P1's state is I when its Upgrade arrives at the directory, and P1 in fact needs data. In this situation, the directory sends a negative acknowledgment (NACK) to P1, and P1 must send a GetM to the directory.

Another interesting feature of the Origin's E state is how requests are satisfied when a pro-

cessor is in E. Consider the case where processor P1 obtains a block in state E. If P2 now sends a GetS to the directory, the directory must consider that P1 (a) might have silently evicted the block, (b) might have an unmodified value of the block (i.e., with the same value as at memory), or (c) might have a modified value of the block. To handle all of these possibilities, the directory responds with data to P2 and also forwards the request to P1. P1 sends P2 either new data (if in M) or just an acknowledgment. P2 must wait for both responses to arrive to know which message's data to use.

One other quirk of the Origin is that it uses only two networks (request and response) instead of the three required to avoid deadlock. A directory protocol has three message types (request, forwarded request, and response) and thus nominally requires three networks. Instead, the Origin protocol detects when deadlock could occur and sends a “backoff” message to a requestor on the response network. The backoff message contains the list of nodes that the request needs to be sent to, and the requestor can then send to them on the request network.

8.8.2 Coherent HyperTransport

Directory protocols were originally developed to meet the needs of highly scalable systems, and the SGI Origin is a classic example of such a system. Recently, however, directory protocols have become attractive even for small- to medium-scale systems because they facilitate the use of point-to-point links in the interconnection network. This advantage of directory protocols motivated the design of AMD's Coherent HyperTransport (HT) [5]. Coherent HT enables glueless connections of AMD processors into small-scale multiprocessors. Perhaps ironically, Coherent HT actually uses broadcasts, thus demonstrating that the appeal of directory protocols in this case is the use of point-to-point links, rather than scalability.

AMD observed that systems with up to eight processor chips can be built with only three point-to-point links per chip and a maximum chip-to-chip distance of three links. Eight processor chips, each of which can have 6-cores in current generation technology, means a system with a respectable 48 cores. To keep the protocol simple, Coherent HT uses a variation on a Dir₀B directory protocol (Section 8.5.2) that stores no stable directory state. Any coherence request sent to the directory is forwarded to all cache controllers (i.e., broadcast). Coherent HT can also be thought of as an example of a null directory cache: requests always miss in the (null) directory cache, so it always broadcasts. Because of the broadcasts, the protocol does not scale to large-scale systems, but that was not the goal.

In a system with Coherent HT, each processor chip contains some number of cores, one or more integrated memory controllers, one or more integrated HyperTransport controllers, and between one and three Coherent HT links to other processor chips. A “node” consists of a processor chip and its associated memory for which it is the home.

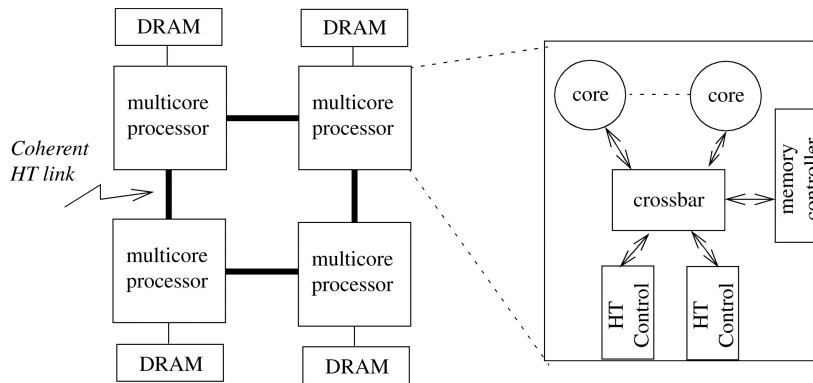

FIGURE 8.16: Four-node Coherent HyperTransport System (adapted from [5]).

There are many viable interconnection network topologies, such as the four-node system shown in Figure 8.16. Significantly, this protocol does not require a total order of coherence requests, which provides greater flexibility for the interconnection network.

A coherence transaction works as follows. A core unicasts a coherence request to the directory controller at the home node, as in a typical directory protocol. Because the directory has no state and thus cannot determine which cores need to observe the request, the directory controller then broadcasts the forwarded request to all cores, including the requestor. (This broadcast is like what happens in a snooping protocol, except that the broadcast is not totally ordered and does not originate with the requestor.) Each core then receives the forwarded request and sends a response (either data or an acknowledgment) to the requestor. Once the requestor has received all of the responses, it sends a message to the directory controller at the home node to complete the transaction.

Looking at this protocol, one can view it as the best or worst of both worlds. Optimistically, it has point-to-point links with no directory state or complexity, and it is sufficiently scalable for up to eight processors. Pessimistically, it has the long three-hop latency of directories—or four hops, if you consider the message from the requestor to the home to complete the transaction, although this message is not on the critical path—with the high broadcast traffic of snooping. In fact, Coherent HT uses even more bandwidth than snooping because all broadcasted forwarded requests generate a response. The drawbacks of Coherent HT motivated an enhanced design called HyperTransport Assist [6].

8.8.3 HyperTransport Assist

For the 12-core AMD Opteron processor-based system code-named Magny Cours, AMD developed HyperTransport Assist [6]. HT Assist enhances Coherent HT by eliminating the need to

broadcast every forwarded coherence request. Instead of the Dir_0B -like protocol of Coherent HT, HT Assist uses a directory cache similar to the design described in Section 8.6.2. Each multicore processor chip has an inclusive directory cache that has a directory entry for every block (a) for which it is the home *and* (b) that is cached anywhere in the system. There is no DRAM directory, thus preserving one of the key features of Coherent HT. A miss in the directory cache indicates that the block is not cached anywhere. HT Assist’s directory cache uses Recall requests to handle situations in which the directory cache is full and needs to add a new entry. Although HT Assist appears from our description thus far to be quite similar to the design in Section 8.6.2, it has several distinguishing features that we present in greater detail.

First, the directory entries provide only enough information to determine whether a coherence request must be forwarded to all cores, forwarded to a single core, or satisfied by the home node’s memory. That is, the directory does not maintain sufficient state to distinguish needing to forward a request to two cores from needing to forward the request to all cores. This design decision eliminated the storage cost of having to maintain the exact number of sharers of each block; instead, two directory states distinguish “one sharer” from “more than one sharer.”

Second, the HT Assist design is careful to avoid incurring a large number of Recalls. AMD adhered to a rule of thumb that there should be at least twice as many directory entries as cached blocks. Interestingly, AMD chose not to send explicit PutS requests; their experiments apparently convinced them that the additional PutS traffic was not worth the limited benefit in terms of a reduction in Recalls.

Third, the directory cache shares the LLC. The LLC is statically partitioned by the BIOS at boot time, and the default is to allocate 1MB to the directory cache and allocate the remaining 5MB to the LLC itself. Each 64-byte block of the LLC that is allocated to the directory cache is interpreted as 16 4-byte directory entries, organized as four 4-way set-associative sets.

8.8.4 Intel QPI

Intel developed its QuickPath Interconnect (QPI) [9, 12] for connecting processor chips starting with the 2008 Intel Core microarchitecture, and QPI first shipped in the Intel Core i7-9xx processor. Prior to this, Intel connected processor chips with a shared-wire bus called the Front-Side Bus (FSB). FSB evolved from a single shared bus to multiple buses, but the FSB approach was fundamentally bottlenecked by the electrical signaling limits of the buses. To overcome this limitation, Intel designed QPI to connect processor chips with point-to-point (i.e., non-bus) links. QPI specifies multiple levels of the networking stack, from physical layer to protocol layer. For purposes of this primer, we focus on the protocol layer here.

QPI supports five stable coherence states, the typical MESI states and the F(orward) state. The F state is a clean, read-only state, and it is distinguished from the S state because a cache with

a block in F may respond with data (i.e., forward the data) to coherence requests. Only one cache may hold a block in F at a given time. The F state is somewhat similar to the O state, but differs in that a block in F is not dirty and can thus be silently evicted; a cache that wishes to evict a block in O must copy the block back to memory. The benefit of the F state is that it allows read-only data to be sourced from a cache, which is often faster than sourcing it from memory (which usually responds to requests when a block is read-only).

QPI provides two different protocol modes, depending on the size of the system: “home snoop” and “source snoop.”

QPI’s Home Snoop mode is effectively a scalable directory protocol (i.e., do not be confused by the word “snoop” in its name²). As with typical directory protocols, a core C1 issues a request to the directory at the home node C2, and the directory forwards that request to only the node(s) that need to see it, say C3 (the owner in M). C3 responds with data to C1 and also sends a message to C2 to notify the directory. When the directory at C2 receives the notification from C3, it sends a “completion” message to C1, at which point C1 may use the data it received from C3. The directory serves as the serialization point in the protocol and resolves message races.

QPI’s Source Snoop protocol mode is designed to have lower-latency coherence transactions, at the expense of not scaling well to large systems with many nodes. A core C1 broadcasts a request to all nodes, including the home. Each core responds to the home with a “snoop response” that indicates what state the block was in at that core; if the block was in state M, then the core sends the block to the requestor in addition to the snoop response to the home. Once the home has received all of the snoop responses for a request, the request has been ordered. At this point, the home either sends data to the requestor (if no core owned the block in M) or a non-data message to the requestor; either message, when received by the requestor, completes the transaction.

Source Snoop’s use of broadcast requests is similar to a snooping protocol, but with the critical difference of the broadcast requests not traveling on a totally ordered broadcast network. Because the network is not totally ordered, the protocol must have a mechanism to resolve races (i.e., when two broadcasts race, such that core C1 sees broadcast A before broadcast B and core C2 sees B before A). This mechanism is provided by the home node, albeit in a way that differs from typical race ordering in directory protocols. Typically, the directory at the requested block’s home orders two racing requests based on which request arrives at the home first. QPI’s Source Snoop, instead, orders the requests based on which request’s snoop responses have all arrived at the home.

Consider the race situation in which block A is initially in state I in the caches of both C1 and C2. C1 and C2 both decide to broadcast GetM requests for A (i.e., send a GetM to the other core and to the home). When each core receives the other core’s GetM, it sends a snoop response

²Intel uses the word “snoop” to refer to what a core does when it receives a coherence request from another node.

to the home. Assume that C2's snoop response arrives at the home before C1's snoop response. In this case, C1's request is ordered first and the home sends data to C1 and informs C1 that there is a race. C1 then sends an acknowledgment to the home, and the home subsequently sends a message to C1 that both completes C1's transaction and tells C1 to send the block to C2. Handling this race is somewhat more complicated than in a typical directory protocol in which requests are ordered when they arrive at the directory.

Source Snoop mode uses more bandwidth than Home Snoop, due to broadcasting, but Source Snoop's common case (no race) transaction latency is less. Source Snoop is somewhat similar to Coherent HyperTransport, but with one key difference. In Coherent HT, a request is unicasted to the home, and the home broadcasts the request. In Source Snoop, the requestor broadcasts the request. Source Snoop thus introduces more complexity in resolving races because there is no single point at which requests can be ordered; Coherent HT uses the home for this purpose.

8.9 DISCUSSION AND THE FUTURE OF DIRECTORY PROTOCOLS

Directory protocols have come to dominate the market. Even in small-scale systems, directory protocols are more common than snooping protocols, largely because they facilitate the use of point-to-point links in the interconnection network. Furthermore, directory protocols are the *only* option for systems requiring scalable cache coherence. Although there are numerous optimizations and implementation tricks that can mitigate the bottlenecks of snooping, fundamentally none of them can eliminate these bottlenecks. For systems that need to scale to hundreds or even thousands of nodes, a directory protocol is the only viable option for coherence. Because of their scalability, we anticipate that directory protocols will continue their dominance for the foreseeable future.

It is possible, though, that future highly scalable systems will not be coherent or at least not coherent across the entire system. Perhaps such systems will be partitioned into subsystems that are coherent, but coherence is not maintained across the subsystems. Or perhaps such systems will follow the lead of supercomputers, like those from Cray, that have either not provided coherence [14] or have provided coherence but restricted what data can be cached [1].

CHAPTER 9

Advanced Topics in Coherence

In Chapters 7 and 8, we have presented snooping and directory coherence protocols in the context of the simplest system models that were sufficient for explaining the fundamental issues of these protocols. In this chapter, we extend our presentation of coherence in several directions. In Section 9.1, we discuss the issues involved in designing coherence protocols for more sophisticated system models. In Section 9.2, we describe optimizations that apply to both snooping and directory protocols. In Section 9.3, we explain how to ensure that a coherence protocol remains live (i.e., avoids deadlock, livelock, and starvation). In Section 9.4, we present token coherence protocols [11], a recently developed class of protocols that subsumes both snooping and directory protocols. We conclude in Section 9.5 with a brief discussion of the future of coherence.

9.1 SYSTEM MODELS

Thus far, we have assumed a simple system model, in which each processor core has a single-level write-back data cache that is physically addressed. This system model omitted numerous features that are typically present in commercial systems, such as instruction caches (Section 9.1.1), translation lookaside buffers (Section 9.1.2), virtually addressed caches (Section 9.1.3), write-through caches (Section 9.1.4), coherent DMA (Section 9.1.5), and multiple levels of caches (Section 9.1.6).

9.1.1 Instruction Caches

All modern cores have at least one level of instruction cache, raising the question of whether and how to support instruction cache coherence. Although truly self-modifying code is rare, cache blocks containing instructions may be modified when the operating system loads a program or library, a just-in-time (JIT) compiler generates code, or a dynamic run-time system re-optimizes a program.

Adding instruction caches to a coherence protocol is superficially straightforward; blocks in an instruction cache are read-only and thus in either stable state I or S. Furthermore, the core never writes directly to the instruction cache; a core modifies code by performing stores to its data cache. Thus, the instruction cache's coherence controller takes action only when it observes a GetM

from another cache (possibly its own L1 data cache) to a block in state S and simply invalidates the block.

Instruction cache coherence differs from data cache coherence for several reasons. Most importantly, once fetched, an instruction may remain buffered in the core's pipeline for many cycles (e.g., consider a core that fills its 128-instruction window with a long sequence of loads, each of which misses all the way to DRAM). Software that modifies code needs some way to know when a write has affected the fetched instruction stream. Some architectures, such as the AMD Opteron, address this issue using a separate structure that tracks which instructions are in the pipeline. If this structure detects a change to an in-flight instruction, it flushes the pipeline. However, because instructions are modified far less frequently than data, other architectures require the software to explicitly manage coherence. For example, the Power architecture provides the *icbi* (instruction cache block invalidate) instruction to invalidate an instruction cache entry.

9.1.2 Translation Lookaside Buffers (TLBs)

Translation lookaside buffers (TLBs) are caches that hold a special type of data: translations from virtual to physical addresses. As with other caches, they must be kept coherent. Like instruction caches, they have not historically participated in the same all-hardware coherence protocols that handle data caches. The traditional approach to TLB coherence is *TLB shutdown* [17], a software-managed coherence scheme that may or may not have some hardware support. In a classic implementation, a core invalidates a translation entry (e.g., by clearing the page table entry's PageValid bit) and sends an inter-processor interrupt to all cores. Each core receives its interrupt, traps to a software handler, either invalidates the specific translation entry from its TLBs or flushes all entries from its TLBs (depending upon the platform). Each core must also ensure that there are no instructions in flight which are using the now-stale translation, typically by flushing the pipeline. Each core then sends an acknowledgment back to the initiating core, using an interprocessor interrupt. The initiating core waits for all of the acknowledgments, ensuring that all stale translation entries have been invalidated, before modifying the translation (or reusing the physical page). Some architectures provide special support to accelerate TLB shutdown. For example, the Power architecture eliminates costly inter-processor interrupts by using a special *tlbie* (TLB invalidate entry) instruction; the initiating core executes a *tlbie* instruction, which broadcasts the invalidated virtual page number to all the cores and completes only once all cores have completed the invalidation.

Recent research proposed eliminating TLB shutdown and instead incorporating the TLBs into the existing all-hardware coherence protocol for the data and instruction caches [15]. This all-hardware solution is more scalable than TLB shutdown, but it requires a modification to the TLBs to enable them to be addressable in the same way as the data and instruction caches. That is, the TLBs must snoop the physical addresses of the blocks that hold translations in memory.

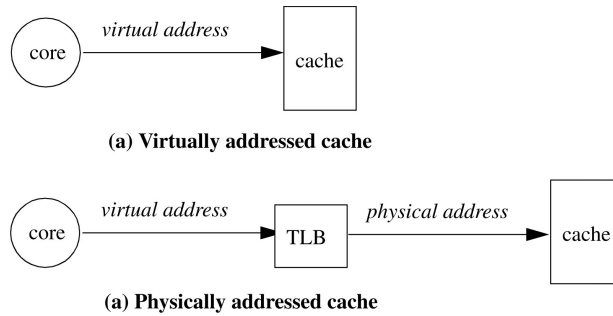

FIGURE 9.1: Physical vs. virtual addressed caches

9.1.3 Virtual Caches

Most caches in current systems—and all caches discussed thus far in this primer—are accessed with physical addresses, yet caches can also be accessed with virtual addresses. We illustrate both options in Figure 9.1. A virtually addressed cache (“virtual cache”) has one key advantage with respect to a physically addressed cache (“physical cache”): the latency of address translation is off the critical path.¹ This latency advantage is appealing for level-one caches, where latency is critical, but generally less compelling for lower level caches where latencies are less critical. Virtual caches, however, pose a few challenges to the architect of a coherence protocol:

- Coherence protocols invariably operate on physical addresses, for compatibility with main memory, which would otherwise require its own TLB. Thus, when a coherence request arrives at a virtual cache, the request’s address must undergo reverse translation to obtain the virtual address with which to access the cache.
- Virtual caches introduce the problem of *synonyms*. Synonyms are multiple virtual addresses that map to the same physical address. Without mechanisms in place to avoid synonyms, it is possible for synonyms to simultaneously exist in a virtual cache. Thus, not only does a virtual cache requires a mechanism for reverse translation but also any given reverse translation could result in multiple virtual addresses.

Because of the complexity of implementing virtual caches, they are rarely used in current systems. However, they have been used in a number of earlier systems, and it is possible that they could become more relevant again in the future.

¹A cache that is virtually indexed and physically tagged has this same advantage without the shortcomings of virtual caches.

9.1.4 Write-Through Caches

Our baseline system model assumes writeback L1 data caches and a shared writeback LLC. The other option, write-through caches, has several advantages and disadvantages. The obvious disadvantages include significantly greater bandwidth and power to write data through to the next lower level of the memory hierarchy. In modern systems, these disadvantages effectively limit the write-through/writeback decision to the L1 cache.

The advantages of write-through L1s include the following:

- A significantly simpler two state VI (Valid and Invalid) coherence protocol. Stores write through to the LLC and invalidate all Valid copies in other caches.
- An L1 eviction requires no action, besides changing the L1 state to Invalid, because the LLC always holds up-to-date data.
- When the LLC handles a coherence request, it can respond immediately because it always has up-to-date data.
- When an L1 observes another core's write, it needs only to change the cache block's state to Invalid. Importantly, this allows the L1 to represent each block's state with a single, clearable flip-flop, eliminating complex arbitration or dual-ported state RAMs.
- Finally, write-through caches also facilitate fault tolerance. Although a detailed discussion is outside the scope of this primer, a write-through L1 cache never holds the only copy of a block because the LLC always holds a valid copy. This allows the L1 to use only parity because it can always just invalidate a block with a parity error.

Write-through caches pose some challenges with multithreaded cores and shared L1 caches. Recall that TSO requires write atomicity, and thus all threads (except the thread performing the store) must see the store at the same time. Thus, if two threads T0 and T1 share the same L1 data cache, T0's store to block A must prevent T1 from accessing the new value until all copies in other caches have been invalidated (or updated). Despite these complications and disadvantages, several current designs use write-through L1 caches, including the Sun Niagara processors and the newly announced AMD Bulldozer.

9.1.5 Coherent Direct Memory Access (DMA)

In Chapter 2, when we first introduced coherence, we observed that incoherence can arise only if there are multiple actors that can read and write to caches and memory. Today, the most obvious collection of actors are the multiple cores on a single chip, but the cache coherence problem first arose in systems with a single core and direct memory access (DMA). A DMA controller is an actor that reads and writes memory under explicit system software control, typically at the page granular-

ity. A DMA operation that reads memory should find the most recent version of each block, even if the block resides in a cache in state M or O. Similarly, a DMA operation that writes memory needs to invalidate all stale copies of the block.

It is straightforward to provide coherent DMA by adding a coherent cache to the DMA controller, and thus having DMA participate in the coherence protocol. In such a model, a DMA controller is indistinguishable from a dedicated core, guaranteeing that DMA reads will always find the most recent version of a block and DMA writes will invalidate all stale copies.

However, adding a coherent cache to a DMA controller is undesirable for several reasons. First, DMA controllers have very different locality patterns than conventional cores, and they stream through memory with little, if any, temporal reuse. Thus, DMA controllers have little use for a cache larger than a single block. Second, when a DMA controller writes a block, it generally writes the entire block. Thus, fetching a block with a GetM is wasteful, since the entire data will be overwritten. Many coherence protocols optimize this case using special coherence operations. We could imagine adding a new GetM-NoData request to the protocols in this primer, which seeks M permission but expects only an acknowledgment message rather than a Data message. Other protocols use a special PutNewData message, which updates memory and invalidates all other copies including those in M and O.

DMA can also be made to work without hardware cache coherence, by requiring the operating system to selectively flush caches. For example, before initiating a DMA to or from a page P, the operating system could force all caches to flush page P using a protocol similar to TLB Shutdown (or using some other page flushing hardware support). This approach is inefficient, and thus generally only seen in some embedded systems, because the operating system must conservatively flush a page even if none of its blocks are in any cache.

9.1.6 Multi-Level Caches and Hierarchical Coherence Protocols

Our baseline system assumes a single multicore chip with two levels of cache: private level-one data (L1) caches for each core and a shared last-level memory-side cache that holds both data and instructions (LLC). But many other combinations of chips and caches are possible. For example, the recent Intel Nehalem and AMD Opteron processors support systems with multiple multicore chips as well as an additional level of private (per core) L2 caches. Figure 9.2 illustrates a system with two multicore processors, each having two cores with private L2 caches between the private L1s and shared LLC.

We next discuss multiple levels of caches on a single multicore chip (Section 9.1.6.1), systems with multiple multicore processors (Section 9.1.6.2), and hierarchical coherence protocols (Section 9.1.6.3).

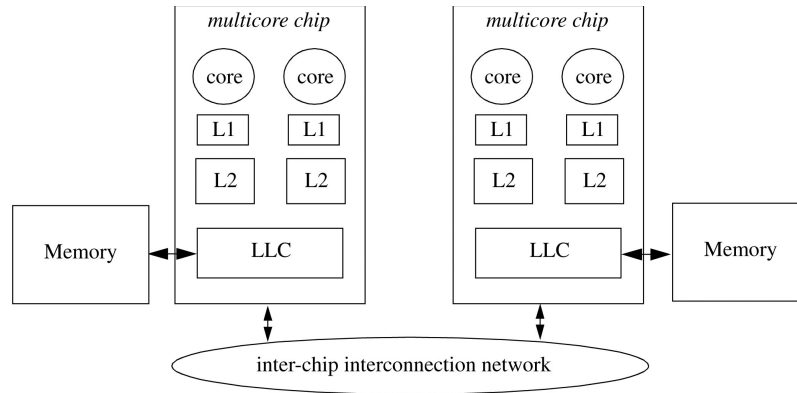

FIGURE 9.2: System with multiple multicore chips

9.1.6.1 Multi-level Caches

With multiple levels of caches, the coherence protocol must be sure to keep all of these caches coherent. Perhaps the most straightforward solution is to treat each cache completely independently. For example, the L1, L2, and LLC could each independently process all incoming coherence requests; this is the approach taken by the AMD Opteron [1].

However, we can also design the cache hierarchy such that not every cache needs to snoop every coherence request. As discussed in Section 8.6, a key design option is whether and which caches to make *inclusive*. An L2 is inclusive if it contains a superset of the blocks in the L1 caches. Consider the case of an inclusive L2 when the L2 snoops a GetM for block B from another core. If B is not in the L2, then there is no need to also snoop the L1 caches because B cannot be in any of them. Thus, an inclusive L2 cache can serve as a filter that reduces the amount of coherence request traffic that must be snooped by the L1 caches. If instead B is in the L2, then B might also be in the L1 caches and then the L1 caches must also snoop the request. This is the approach taken by the AMD Bulldozer.

Inclusion's benefit—the reduction in L1 snoop bandwidth—must be traded off against the space wasted by redundant storage of inclusive blocks. The cache hierarchy can hold a greater number of distinct blocks if it is *exclusive* (i.e., if a block is in the L2 then it is not in the L1 caches) or non-inclusive (neither inclusive nor exclusive). Another reason not to provide inclusion is to avoid the complexity of maintaining inclusion (i.e., invalidating a block from the L1 when an L2 evicts that block).

9.1.6.2 Multiple Multicore Processors

Larger systems can be built by composing multiple multicore processor chips. While a full treatment of scalable systems is beyond the scope of this primer, we examine one key issue: how to

use the LLC. In single-chip systems, the LLC is a memory-side cache logically associated with memory and thus can be largely ignored as far as coherence is concerned. In multi-chip systems, the LLC can alternatively be viewed as another level of the memory hierarchy. We present the options from the perspective of a given chip (the “local” chip) and its local memory; other chips are “remote” chips. The LLC could be used as:

- A memory-side cache that holds blocks recently requested from the local memory. The requests could be either from only the local chip or from both local and remote chips.
- A core-side cache that holds blocks recently requested by the cores on the chip. The blocks in the LLC could have homes on either this chip or other chips. In this case, the coherence protocol must usually operate among the LLCs and memories of the multiple multicore chips.

The LLC could also be used for both purposes, in a hybrid scheme. In a hybrid approach, the architects would have to decide how to allocate the LLC to these different demands.

9.1.6.3 Hierarchical Coherence Protocols

The protocols described in previous chapters are *flat* protocols, in that there was a single coherence protocol that every cache controller treats identically. However, once we introduce multiple levels of caches, we introduce the possible need for *hierarchical* coherence protocols.

Some systems are naturally hierarchical, including systems comprised of multiple multicore chips. Within each chip, there could be an intra-chip protocol, and there could be an inter-chip protocol across the chips. Coherence requests that can be satisfied by the intra-chip protocol do not interact with the inter-chip protocol; only when a request cannot be satisfied by another node on the chip does the request get promoted to the inter-chip protocol.

The choice of protocol at one level is largely independent of the choice at another level. For example, an intra-chip snooping protocol can be made compatible with an inter-chip directory protocol. Each chip would require a single directory controller that considers the entire chip to be a single node in the directory protocol. The inter-chip directory protocol could be identical to one of the directory protocols presented in Chapter 8, with the directory state naturally represented in a coarse fashion. Another possible hierarchical system could have directory protocols for both the intra- and inter-chip protocols, and the two directory protocols could be the same or even different from each other.

An advantage of hierarchical protocols for hierarchical systems is that it enables the design of a simple, potentially non-scalable intra-chip design for the commodity chip. When designing a chip, it would be beneficial to not have to design a single protocol that scales to the largest possible

number of cores that could exist in a system. Such a protocol is likely to be overkill for the vast majority of systems that are comprised of a single chip.

There are numerous examples of hierarchical protocols for hierarchical systems. The Sun Wildfire prototype [5] connects multiple snooping systems together with a higher level directory protocol. The AlphaServer GS320 [4] has two levels of directory protocols, one within each quad-processor block and another across these blocks. The Stanford DASH machine [10] consisted of multiple snooping systems connected by a higher level directory protocol.

In a system with hundreds or thousands of cores, it might not make much sense to have a single coherence protocol. The system may be more likely to be divided, either statically or dynamically, into domains that each run a separate workload or separate virtual machine. In such a system, it may make sense to implement a hierarchical protocol that optimizes for intra-domain sharing yet still permits inter-domain sharing. Recent work by Marty and Hill [12] superposes a hierarchical coherence protocol on top of a multicore chip with a flat design. This design enables the common case—intra-domain sharing—to be fast while still allowing sharing across domains.

9.2 PERFORMANCE OPTIMIZATIONS

There is a long history of research into optimizing the performance of coherence protocols. Rather than present a high-level survey, we focus on two optimizations that are largely independent of whether the underlying coherence protocol is snooping or directory. Why these two optimizations? Because they can be effective and they illustrate the kinds of optimizations that are possible.

9.2.1 Migratory Sharing Optimization

In many multithreaded programs, a common phenomenon is *migratory sharing*. For example, one core may read and then write a data block, then a second core may read and write it, and so on. This pattern commonly arises from critical sections (e.g., the lock variable itself) in which the data block migrates from one core to another. In a typical protocol, each core performs a GetS transaction to read the data and then a subsequent GetM transaction to get write permission for the same block. However, if the system can predict that the data conforms to a migratory sharing pattern, cores could get an exclusive copy of the block when they first read it, thus reducing both the latency and bandwidth to access the data [2, 14, 16]. The migratory optimization is similar to the E state optimization, except that it also needs to return an exclusive copy when the block is in state M in some cache, not just when the block is in state I in all caches.

There are two basic approaches to optimizing migratory sharing. First, one can use some hardware predictor to predict that a particular block exhibits a migratory sharing pattern and is-

sue a GetM rather than a GetS on a load miss. This approach requires no change to the coherence protocol but introduces a few challenges:

- Predicting migratory sharing: we must design a hardware mechanism to predict when a block is undergoing migratory sharing. A simple approach is to use a table to record which blocks were first obtained with a GetS and then subsequently written, requiring a GetM. On each load miss, the coherence controller could consult the predictor to determine whether a block exhibits a migratory sharing pattern. If so, it could issue a GetM request, rather than a GetS.
- Mispredictions: if a block is not migrating, then this optimization can hurt performance. Consider the extreme case of a system in which cores issue only GetM requests. Such a system would never permit multiple cores to share a block in a read-only state.

Alternatively, we can extend the coherence protocol with an additional Migratory M (MM) state. The MM state is equivalent to the state M, from a coherence perspective (i.e., dirty, exclusive, owned), but it indicates that the block was obtained by a GetS in response to a predicted migratory sharing pattern. If the local core proceeds to modify a block in MM, reinforcing the migratory sharing pattern, it changes the block to state M. If a core in state M receives a GetS from another core, it predicts that the access will be migratory and sends exclusive data (invalidating its own copy). If the Other-GetS finds the block in state MM, the migratory pattern has been broken and the core sends a shared copy and reverts to S (or possibly O). Thus, if many cores make GetS requests (without subsequent stores and GetM requests), all cores will receive S copies.

Migratory sharing is just one example of a phenomenon that, if detected, can be exploited to improve the performance of coherence protocols. There have been many schemes that target specific phenomena, as well as more general approaches to predicting coherence events [13].

9.2.2 False Sharing Optimizations

One performance problem that can plague coherence protocols is *false sharing*. False sharing occurs when two cores are reading and writing different data that happen to reside on the same cache block. Even though the cores are not actually sharing the data on the block (i.e., the sharing is false), there can be a significant amount of coherence traffic between the cores for the block. This coherence traffic hurts performance when a core is waiting for coherence permissions to access a block, and it increases the load on the interconnection network. The likelihood of false sharing occurring is a function of the block size—a larger block can hold more unrelated pieces of data and thus larger

blocks are more prone to false sharing—and the workload. There are at least two optimizations to mitigate the impact of false sharing:

Sub-block Coherence

Without reducing the block size, we can perform coherence at a finer, sub-block granularity [7]. Thus, it is possible for a block in a cache to have different coherence states for different sub-blocks. Sub-blocking reduces false sharing, but it requires extra state bits for each block to hold the sub-block states.

Speculation

An architect can develop a hardware mechanism to predict when a block that is invalid in a cache is the victim of false sharing [6]. If the predictor believes the block is invalid due to false sharing, the core can speculatively use the data in the block until it obtains coherence permissions to the block. If the prediction was correct, this speculation overcomes the latency penalty of false sharing, but it does not reduce the traffic on the interconnection network.

9.3 MAINTAINING LIVENESS

In Chapter 2, we defined coherence and the invariants that must be maintained by a coherence protocol. These invariants are *safety* invariants; if these invariants are maintained, then the protocol will never allow unsafe (incorrect) behavior. Facetiously, it is easy to provide safety because an unplugged computer never does anything incorrect! The key is to provide both safety and *liveness*, where providing liveness requires the prevention of three classes of situations: deadlock, livelock, and starvation.

9.3.1 Deadlock

As discussed briefly in Section 8.2.3, deadlock is the situation in which two or more actors wait for each other to perform some action, and thus never make progress. Typically, deadlock results from a cycle of resource dependences. Consider the simple case of two nodes A and B and two resources X and Y. Assume A holds resource X and B holds resource Y. If A requests Y and B requests X, then unless one node relinquishes the resource it already holds, these two nodes will deadlock. We illustrate this cyclical dependence graph in Figure 9.3. More generally, deadlock can result from cycles involving many nodes and resources. Note that partial deadlocks (e.g., the simple case of deadlock between only nodes A and B) can quickly become complete system deadlocks when other nodes wait for deadlocked nodes to perform some action (e.g., node C requests resource X).

FIGURE 9.3: Example of deadlock due to cyclical resource dependences. Circles are nodes and squares are resources. An arc that ends at a resource denotes a request for that resource. An arc that starts at a resource denotes the holder of that resource.

Protocol Deadlocks

In coherence protocols, deadlock can arise at the protocol level, at cache resource allocation, and in the network. Protocol deadlocks arise when a coherence controller waits for a message that will never be sent. For example, consider a (buggy) directory protocol that does not wait for a Put-Ack after sending a PutS, and instead immediately transitions to state I. If the directory controller sends an Inv (e.g., in response to core C1's GetM request) to core C0 at the same time that core C0 sends a PutS to the directory, then C1 will never get an Inv-Ack from core C0 and will deadlock waiting for it. Such deadlocks represent protocol errors and usually arise from untested race conditions.

Cache Resource Deadlocks

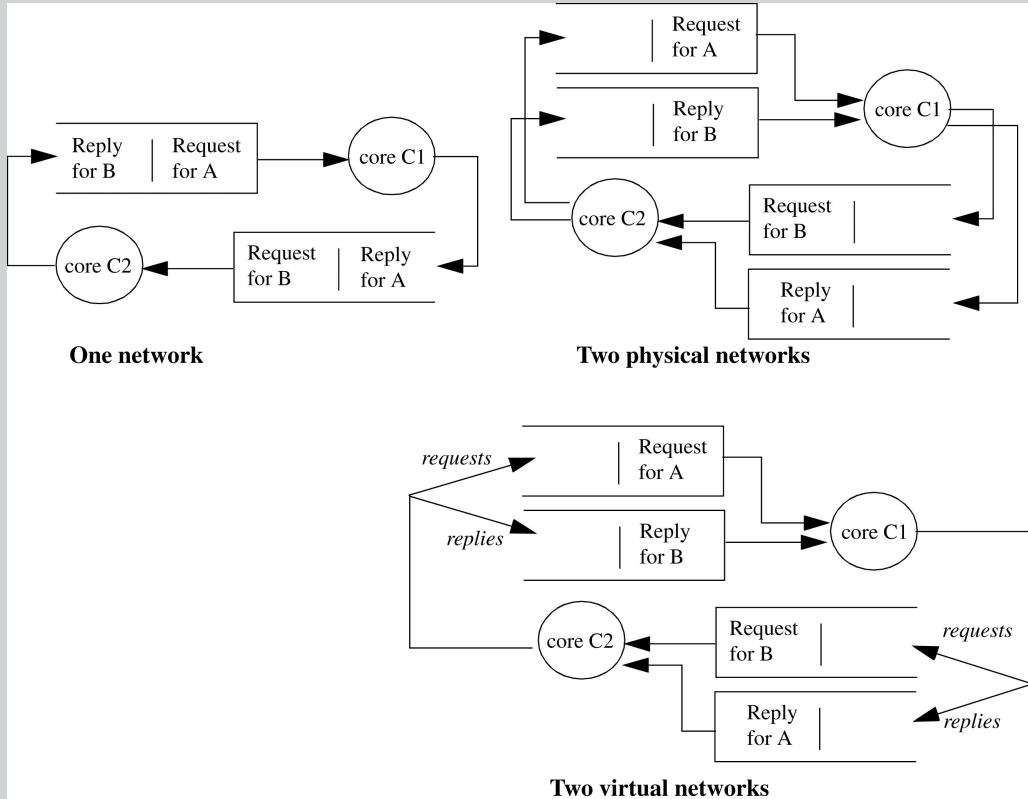

Cache resource deadlocks arise when a cache controller must allocate a resource before performing some action. These deadlocks typically arise either when handling another core's request or on writebacks. For example, consider a cache controller that has a set of shared buffers (e.g., transaction buffer entries, or TBEs) that may be allocated *both* when the core initiates a coherence request *and* when servicing another core's request. If the core issues enough coherence requests to allocate all the buffers, then it cannot process another core's request until it completes one of its own. If all cores reach this state, then the system deadlocks.

Protocol-Dependent Network Deadlocks

There are two causes of network deadlocks: deadlocks due to buggy routing algorithms, which are independent of the types of messages and the coherence protocol, and network deadlocks that arise because of the particular messages being exchanged during coherence protocol operation. We focus here on this latter category of protocol-dependent network deadlocks. Consider a directory protocol in which a request message may lead to a forwarded request and a forwarded request may lead to a response. The protocol must ensure three invariants to avoid cyclic dependences and thus deadlock.

Sidebar: Virtual Networks

Instead of using physically distinct networks, we can use distinct *virtual networks*. Consider two cores that are connected with a single point-to-point link. At the end of each link is a FIFO queue to hold incoming messages before the receiving core can process them. This single network is shown below on the left. To add another physical network, as shown below on the right, we duplicate the links and the FIFO queues. Requests travel on one physical network, and replies travel on the other physical network.

To avoid the cost of replicating the links and switches (switches not shown in figures), we can add a virtual network, as illustrated. The only cost of a virtual network is an additional FIFO queue at each switch and endpoint in the network. Adding the second virtual network in this example allows requests to not get stuck behind replies.

Virtual networks are related to virtual channels [3], and some papers use the terms interchangeably. However, we prefer to distinguish between them because they address different types of deadlocks. Virtual networks prevent messages of different classes from blocking each other and thus avoid message-level deadlocks.

Virtual channels are used at the network level to avoid deadlocks due to routing, regardless of the message types. To avoid routing deadlock, messages travel on multiple virtual channels (e.g., a message traveling west in a 2D torus might be required to use virtual channel 2). A virtual channel, like a virtual network, is implemented as an extra FIFO queue at each switch and end point in the network. Virtual channels are orthogonal to virtual networks; each virtual network may have some number of virtual channels to avoid routing deadlock

- As explained in Section 8.2.3, each message class must travel on its own network. The networks may be physical or virtual [see sidebar on “virtual networks”], but the key is avoiding situations in which a message of one class becomes stuck behind a message of another class in a FIFO buffer. In this example, requests, forwarded requests, and responses all travel on separate networks. A coherence controller thus has three incoming FIFOs, one for each network.
- Message classes must have a dependence order. If a message of class A can cause a coherence controller to issue a message of class B, then a coherence controller may not stall the processing of an incoming class B message while waiting for a class A message. In the directory example, a coherence controller cannot stall the processing of a forwarded request while waiting for a request to arrive, nor can it stall the processing of a response while waiting for a forwarded request.
- The last message class in this chain of dependences—the response message, in this directory example—must always be “sunk.” That is, if a coherence controller receives a response message, there must be no message class than can prevent it from being removed from its incoming queue.

These three invariants eliminate the possibility of a cycle. Even though a request can be stalled while waiting for responses or forwarded requests, every request will eventually be processed because the number of responses and forwarded requests is bounded by the number of outstanding transactions.

9.3.2 Livelock

Livelock is a situation in which two or more actors perform actions and change states, yet never make progress. Livelock is a special case of starvation, discussed next. Livelock occurs most frequently in coherence protocols that use negative acknowledgment messages (NACKs). A node may issue a coherence request, but receive a NACK, prompting a retry. If contention or some repeatable race with another node causes this case to recur indefinitely, then the nodes livelock. The protocols in this primer do not use NACKs, so we focus on another well-known livelock involving coherence permissions that can arise in these protocols.

This cause of livelock is the so-called “window of vulnerability” problem [8], an example of which is illustrated in Table 9.1. Consider a snooping protocol in which Core C1 issues a GetS request for block B and changes B’s state to IS^{AD} (in I, going to S, waiting for own GetS and data). At some point later, C1 observes its own GetS on the bus and changes B’s state to state IS^D . Between when B goes to state IS^D and when C1 receives the data response, it is vulnerable to observing a GetM request for B from another core on the bus. In an optimized protocol, like the protocol in

TABLE 9.1: Livelock Example for Core C1 Trying to Load Block B in a Snooping Protocol.

cycle	event (all for block B)	Core C1's state for B
0	<i>initial state</i>	I
1	load request, issue GetS to bus	IS ^{AD}
2	observe Own-GetS on bus	IS ^D
3	observe Other-GetM on bus	IS ^{DI}
4	receive data for Own-GetS	I
5	re-issue GetS to bus	IS ^{AD}
6	observe Own-GetS on bus	IS ^D
7	observe Other-GetM on bus	IS ^{DI}
8	receive data for Own-GetS	I
9	Etc. (never completing the load)	

Section 7.5.5, if a GetM arrives for B in state IS^D, C1 will change B's state to IS^{DI}. In this transient state, when C1 later receives the data response, C1 changes B's state to I. Because C1 cannot perform a load to a block in I, it must issue another GetS for B. However, this next GetS is just as susceptible to the window of vulnerability problem, and thus C1 may never make forward progress. The core is still active, and thus the system is not deadlocked, but it never makes forward progress. Somewhat perversely, this situation is most likely to arise for highly contended blocks, which means that most or all of the cores are likely to simultaneously be stuck and thus the system can livelock.

This window of vulnerability can be closed by requiring that C1 perform at least one load when it receives the data response. This load *logically appears to occur* at the time at which C1's GetS is ordered (e.g., on the bus in a snooping protocol) and thus does not violate coherence. However, if certain conditions are not satisfied, performing this load could violate the memory consistency model. Satisfying these conditions is sometimes known as the Peekaboo problem, and we discuss it in more detail in the sidebar. The simplest solution to the Peekaboo problem is to perform the load in the window of vulnerability *if and only if* that load was the oldest load in program order when the coherence request was first issued. A complete analysis of why this solution is sufficient is outside the scope of this primer, but intuitively the problem cannot arise if a core issues coherence requests one at a time in the order of demand misses.

Sidebar: Peekaboo Coherence Problem

Table 9.2 illustrates what is sometimes called the Peekaboo Coherence problem. In this example, the locations A and B are initially zero, core C0 writes A first and then B, and core C1 reads B first and then A. Under both the SC and TSO memory consistency models, the only illegal outcome is r1=1 and r2=0. This example execution uses the optimized directory protocol from Section 8.7.2, but elides the directory controller’s actions (which are not pertinent to the example). PrefetchS is the one new operation in this example, which issues a GetS request if a readable block does not already reside in the cache.

The Peekaboo problem arises when a block is prefetched, invalidated before permission is received, and then a demand reference occurs. If we perform the demand reference when the prefetched but already invalidated Data arrives, then the demand reference is effectively ordered at the time the block was invalidated. In this example, C1’s load A is effectively ordered at time 4 (when C1 receives the Inv for block A), while C1’s earlier (in program order) load B is ordered at time 7. Reordering these two loads violates both SC and TSO. Note that this problem can arise whether the prefetch operation results from an explicit prefetch instruction, hardware prefetcher, or speculative execution. This problem can also arise in optimized snooping protocols, such as the one in Section 7.5.5.

TABLE 9.2: Example of Peekaboo Coherence Problem

Time	Core C0 A=B=0 initially store A = 1 store B = 1	Core C1 prefetchS A (prefetch for read-only access) load r1 = B load r2 = A
0	A:M[0] B:M[0]	A:I B:I
1		A: prefetchS miss, issue GetS/IS ^D
2	A: receive Fwd-GetS, send Data[0]/S	
3	A: store miss; issue GetM/SM ^{AD}	
4	A: receive Data[0](ack=1)/SM ^A	A: receive Inv, send Inv-Ack/IS ^{DI}
5	A: receive Inv-Ack, perform store/M[1]	
6	B: store hit/M[1]	
7		B: load miss, issue GetS/IS ^D
8	B: receive Fwd-GetS, send Data[1]/S[1]	
9		B: receive Data[1], perform load r1=1/S[1]
10		A: load miss, stall/IS ^{DI}
11		A: receive Data[0], perform load r2=0/I
Core C1 observes A = 0 and B = 1, effectively reordering the loads.		

This same window of vulnerability exists for stores to blocks in IM^D_S , IM^D_{SI} , or IM^D_I . In these cases, the store to the block is never performed because the block's state at the end of the transaction is either I or S, which is insufficient for performing a store. Fortunately, the same solution we presented for the load in IS^D_I applies to stores in these states. A core that issues a GetM must perform at least one store when it receives the data, and the core must forward this newly written data to the other core(s) that requested the block in S and/or M between when it observes its own GetM and when it receives the data in response to its GetM. Note that the same restriction needed to avoid the Peekaboo problem still applies: namely, perform the store if and only if the store was the oldest load or store in program order at the time the coherence request was issued.

9.3.3 Starvation

Starvation is a situation in which one or more cores fail to make forward progress while other cores are still actively making forward progress. The cores not making progress are considered to be starved. There are several root causes of starvation, but they tend to fall into two categories: unfair arbitration and incorrect use of negative acknowledgments.

Starvation can arise when at least one core cannot obtain a critical resource because the resource is always obtained or held by other cores. A classic example of this is an unfair bus arbitration mechanism in a bus-based snooping protocol. Consider a bus in which access to the bus is granted in a fixed priority order. If Core C1 wishes to make a request, it can make a request. If C2 wishes to make a request, it may make the request only if C1 has not first requested the bus. C3 must defer to C1 and C2, etc. In such a system, a core with a low priority may never gain permission to make a request and will thus starve. This well-known problem also has a well-known solution: fair arbitration.

The other main class of starvation causes is the incorrect use of negative acknowledgments (NACKs) in coherence protocols. In some protocols, a coherence controller that receives a coherence request may send a NACK to the requestor (often used in verb form as “the controller NACKed the request”), informing the requestor that the request was not satisfied and must be re-issued. NACKs are generally used by protocols to simplify situations in which there is another transaction in progress for the requested block. For example, in some directory protocols, the directory can NACK a request if the requested block is already in the midst of a transaction. Solving these protocol race conditions with NACKs appears, at least at first blush, to be conceptually easier than designing the protocol to handle some of these rare and complicated situations. However, the challenge is ensuring that a NACKed request eventually succeeds. Guaranteeing a lack of starvation, regardless of how many cores are requesting the same block at the same time, is challenging; one of the authors of this primer confesses to having designed a protocol with NACKs that led to starvation.

9.4 TOKEN COHERENCE

Until fairly recently, coherence protocols could be classified as either snooping or directory or perhaps a hybrid of the two. There were many variants of each class and several hybrids, but protocols were fundamentally some combination of snooping and directory. In 2003, Martin et al. proposed a third protocol classification called *Token Coherence* [11]. There are two key ideas behind Token Coherence (TC).

TC protocols associate tokens with each block instead of state bits. There is a fixed number of tokens per block, and the cores can exchange—but not create or destroy—these tokens. A core with one or more tokens for a block can read the block, and a core with all of the tokens for a block can read or write to the block.

A TC protocol consists of two distinct parts: a correctness substrate and a performance protocol. The correctness substrate is responsible for ensuring safety (tokens are conserved) and liveness (all requests are eventually satisfied). The performance protocol specifies what a cache controller does on a cache miss. For example, in the TokenB performance protocol, all coherence requests are broadcast. In the TokenM protocol, coherence requests are multicast to a predicted set of sharers.

Token Coherence subsumes snooping and directory protocols, in that snooping and directory protocols can be interpreted as TC protocols. For example, an MSI snooping protocol is equivalent to a TC protocol with a broadcast performance protocol. The MSI states are equivalent to a core having all/some/none of the tokens for a block.

9.5 THE FUTURE OF COHERENCE

Almost since coherence's invention, some have predicted that it will soon go away because it adds hardware cost to store extra state, send extra messages, and verify that all is correct. However, we predict that coherence will remain commonly implemented because in our judgment, the software cost of dealing with incoherence is often substantial and borne by a broader group of software engineers rather than the few hardware designers that confront implementing coherence.

Author Biographies

Daniel J. Sorin is an associate professor of Electrical and Computer Engineering and of Computer Science at Duke University. His research interests are in computer architecture, including dependable architectures, verification-aware processor design, and memory system design. He received a PhD and MS in electrical and computer engineering from the University of Wisconsin, and he received a BSE in electrical engineering from Duke University. He is the recipient of an NSF Career Award and a Warren Faculty Scholarship at Duke. He is the author of a previous Synthesis Lecture, “Fault Tolerant Computer Architecture” (2009).

Mark D. Hill (<http://www.cs.wisc.edu/~markhill>) is Professor of Computer Sciences and Electrical and Computer Engineering at the University of Wisconsin, Madison. He is the inventor of the widely used 3C model of cache behavior (compulsory, capacity, and conflict misses). He currently co-leads the Wisconsin Multifacet project that develops innovative multiprocessor designs and simulation methods (e.g., GEMS and gem5). He earned a Ph.D. and M.S. from the University of California, Berkeley and a B.S.E. from the University of Michigan, Ann Arbor. Hill is an ACM Fellow, a Fellow of the IEEE, recipient of the ACM SIGARCH Distinguished Service Award, and has won several university awards (Romnes, Vilas Associate, and Kellett). He has had visiting appointments at Sun Microsystems, Universidad Politecnica de Catalunya, Columbia University, AMD, and the University of Washington.

Prof. David A. Wood is Professor of Computer Sciences and Electrical and Computer Engineering at the University of Wisconsin, Madison. Dr. Wood has a Ph.D. in Computer Science (1990) from UC Berkeley. Dr. Wood is an ACM Fellow (2006), IEEE Fellow (2004), UW Vilas Associate (2011), UW Romnes Fellow (1999), and NSF PYI (1991). Dr. Wood is Area Editor (Computer Systems) of ACM TOMACS, is Associate Editor of ACM TACO, served as Program Committee Chairman of ASPLOS-X (2002), and has served on numerous program committees. Dr. Wood has published over 80 technical papers and is an inventor on a dozen U.S. and international patents. Dr. Wood co-leads the Wisconsin Multifacet project, which distributes the widely used Wisconsin GEMS full-system multiprocessor simulation system.
